ABSTRACT

Background

Asthma guidelines aim to guide health practitioners to optimise treatment for patients to minimise symptoms, improve or maintain good lung function, and prevent acute exacerbations. The principle of asthma guidelines is based on a step-up or step-down regimen of asthma medications to maximise health using minimum doses. Fractional exhaled nitric oxide (FeNO) is a marker of eosinophilic inflammation and tailoring asthma medications in accordance to airway eosinophilic levels may improve asthma outcomes such as indices of control or reduce exacerbations, or both.

Objectives

To evaluate the efficacy of tailoring asthma interventions based on fractional exhaled nitric oxide (FeNO), in comparison to not using FeNO, that is, management based on clinical symptoms (with or without spirometry/peak flow) or asthma guidelines (or both), for asthma-related outcomes in children.

Search methods

We searched the Cochrane Airways Group Specialised Register of Trials, the Cochrane Central Register of Controlled Trials (CENTRAL), MEDLINE, Embase and reference lists of articles. The last searches were in June 2016.

Selection criteria

All randomised controlled trials (RCTs) comparing adjustment of asthma medications based on FeNO levels compared to those not using FeNO, that is, management based on clinical symptoms or asthma guidelines (or both) involving children.

Data collection and analysis

We reviewed results of searches against predetermined criteria for inclusion. Two review authors independently selected relevant studies, assessed trial quality and extracted data. We contacted study authors for further information with responses provided from three.
Main results

The review included nine studies; these studies differed in a variety of ways including definition of asthma exacerbations, FeNO cut-off levels used (12 parts per billion (ppb) to 30 ppb), the way in which FeNO was used to adjust therapy and duration of study (6 to 12 months). Of 1426 children randomised, 1329 completed the studies. The inclusion criteria for the participants in each study varied but all had a diagnosis of asthma. There was a significant difference in the number of children having one or more asthma exacerbations over the study period, they were significantly lower in the FeNO group in comparison to the control group (odds ratio (OR) 0.58, 95% confidence interval (CI) 0.45 to 0.75; 1279 participants; 8 studies). The number needed to treat for an additional beneficial outcome (NNTB) over 52 weeks was 9 (95% CI 6 to 15). There was no difference between the groups when comparing exacerbation rates (mean difference (MD) -0.37, 95% CI -0.8 to 0.06; 736 participants; 4 studies; I² = 67%). The number of children in the FeNO group requiring oral corticosteroid courses was lower in comparison to the children in the control group (OR 0.63, 95% CI 0.48 to 0.83; 1169 participants; 7 studies; I² = 0%). There was no statistically significant difference between the groups for exacerbations requiring hospitalisation (OR 0.75, 95% CI 0.41 to 1.36; 1110 participants; 6 studies; I² = 0%). There were no significant differences between the groups for any of the secondary outcomes (forced expiratory volume in one second (FEV₁), FeNO levels, symptom scores or inhaled corticosteroid doses at final visit). The included studies recorded no adverse events.

Three studies had inadequate blinding and were thus considered to have a high risk of bias. However, when these studies were removed in subgroup analysis, the difference between the groups for the primary outcome (exacerbations) remained statistically significant. The GRADE quality of the evidence ranged from moderate (for the outcome ‘Number of participants who had one or more exacerbations over the study period’) to very low (for the outcome ‘Exacerbation rates’), based on lack of blinding, statistical heterogeneity and imprecision.

Authors’ conclusions

In this updated review with five new included studies, tailoring asthma medications based on FeNO levels (in comparison with primarily guideline management) significantly decreased the number of children who had one or more exacerbations over the study period but did not impact on the day-to-day clinical symptoms or inhaled corticosteroid doses. Therefore, the use of FeNO to guide asthma therapy in children may be beneficial in a subset of children, it cannot be universally recommended for all children with asthma.

Further RCTs need to be conducted and these should encompass different asthma severities, different settings including primary care and less affluent settings, and consider different FeNO cut-offs.

PLAIN LANGUAGE SUMMARY

Can exhaled nitric oxide be used to adjust asthma medications in children with asthma?

Background

We investigated whether exhaled (breathing out) nitric oxide (a marker in the breath which can show a type of lung inflammation) can be useful to adjust asthma medications in children with asthma instead of following the usual ways that asthma medications are adjusted to get the best dose to control the asthma. Exhaled nitric oxide levels are easily obtained by getting the person to breathe into a commercially available analyser.

Study characteristics

We included all randomised controlled trials that compared adjustment of asthma medications by either usual clinical care (control group) versus using exhaled nitric oxide. The participants included in the trials had asthma diagnosed as per relevant asthma guidelines.

The evidence is current to June 2016 when the searches were last completed.

The review included nine studies (involving 1426 children) that varied in a several ways including length of the study, exhaled nitric oxide cut-off levels used for altering medicines and the way each study defined flare-ups or attacks (called exacerbations). The studies ranged from 6 to 12 months in length. The exhaled nitric oxide cut-off values used by the different studies as a basis for decreasing or increasing medicines also varied.

The mean age of the participants ranged from 10 to 14 years old.

Key results
In this review, we found that guiding asthma medicines based on exhaled nitric oxide (compared to a control group) was beneficial in reducing the number of children who had at least one exacerbation during the study. In the control group where therapy was guided according to clinical symptoms, 40 children out of 100 had at least one exacerbation over 48.5 weeks, compared to 28 out of 100 children where treatment was guided by exhaled nitric oxide. However, we found no difference between groups in other measures of asthma severity that impact on day-to-day clinical symptoms or inhaled corticosteroid dose (medications used to control asthma). Therefore, using exhaled nitric oxide levels to adjust asthma therapy may reduce the number of attacks that children with asthma have but does not impact on the day-to-day symptoms.

Quality of the evidence

The level of evidence found ranged from moderate, when comparing the two groups for the number of children who had one or more exacerbations, to very low when comparing the number of exacerbations.
### Summary of Findings for the Main Comparison

**Tailoring asthma treatment using fractional exhaled nitric oxide vs clinical symptoms**

**Patient or population:** children with asthma  
**Setting:** outpatient  
**Intervention:** asthma treatment tailored on FeNO  
**Comparison:** asthma treatment tailored on clinical symptoms

The risk in the intervention group (and its 95% confidence interval) is based on the assumed risk in the comparison group and the relative effect of the intervention (and its 95% CI).

CI: confidence interval; FeNO: fractional exhaled nitric oxide; ICS: inhaled corticosteroid; MD: mean difference; OR: odds ratio; RCT: randomised controlled trial

### GRADE Working Group grades of evidence

**High quality:** We are very confident that the true effect lies close to that of the estimate of the effect.

**Moderate quality:** We are moderately confident in the effect estimate: The true effect is likely to be close to the estimate of the effect, but there is a possibility that it is substantially different.

**Low quality:** Our confidence in the effect estimate is limited: The true effect may be substantially different from the estimate of the effect.

**Very low quality:** We have very little confidence in the effect estimate: The true effect is likely to be substantially different from the estimate of effect.

---

1. Three studies carrying 23.7% of the analysis weight were at high risk of performance bias and detection bias due to the lack of blinding (downgraded one level risk of bias) ([de Jongste 2008; Verini 2010; Voorend-van Bergen 2015](#)).

2. One study carrying 11% of the analysis weight was open labelled which may have introduced detection bias ([Verini 2010](#)). A random-effects sensitivity analysis substantially changed the result to MD -0.37 (95% CI -0.8 to 0.06). There was also statistical heterogeneity in the analysis (I² = 67%, P = 0.03) (downgrade three levels for risk of bias, imprecision and heterogeneity).

3. One study carrying 47% of the analysis weight was single blinded and participants were aware of their allocation group (downgraded one level for performance bias) ([Voorend-van Bergen 2015](#)).
Background

Description of the condition

Asthma is one of the most common chronic diseases in children. Acute attacks (exacerbations) are common in children with asthma and some require more intensive treatment in hospital. Hospitalisations for asthma account for 12% to 21% (Anderson 2007; Akinbami 2009) of hospitalisations worldwide (Gupta 2006). Thus, prevention of exacerbations, particularly severe exacerbations, is one goal of good asthma management. The second component in asthma management is monitoring of asthma control (by subjective and objective measures) (National Asthma Council 2014; BTS/SIGN 2016; GINA 2016). Subjective measures usually involve a series of questions used for clinical assessment, diary cards and quality of life (QoL) questionnaires. Traditional objective methods include peak flow, spirometry and degree of airway hyper-responsiveness (Zacharasiewicz 2005). Newer and arguably more sensitive methods include measurement of airway inflammation such as airway cellularity in induced sputum or fractional exhaled nitric oxide (FeNO).

Airway inflammation associated with asthma can be eosinophilic or neutrophilic (Douwes 2002). Arguably, asthma management is best tailored in accordance to the type of airway inflammation, as corticosteroids are more beneficial in eosinophilic inflammation (Wardlaw 2000); inhaled corticosteroids (ICS) reduce exacerbations and improve symptoms and asthma control (Wardlaw 2000). There are several ways to quantify airway eosinophilic inflammation, such as determining the percentage of eosinophils in the sputum and FeNO. FeNO correlates with other markers of asthma, for example, eosinophilia in induced sputum (Jatakanon 1998), and bronchial reactivity in non-steroid treated people (Dupont 1998).

Description of the intervention

The principle of asthma management is based on a step-up or step-down regimen of asthma medications to reduce airway inflammation, control symptoms and reduce exacerbations. Therefore, tailoring of asthma medications in accordance to levels reflective of airway eosinophilia may improve asthma control or reduce exacerbations, or both. Obtaining induced sputum samples and sputum analysis is labour intensive and not widely available in most routine clinical settings. Hypertonic saline, used to induce sputum may also temporarily increase asthma symptoms (such as wheeze, cough and chest tightness) and sputum is not always successfully obtained in young children. Thus, measures of FeNO confer some advantage over measurements of sputum eosinophils. However, assessment of FeNO levels do not provide any data on non-eosinophilic inflammation and the equipment required to measure FeNO is relatively expensive.

FeNO levels can be measured using commercially available analysers. These analysers vary in several ways that include methods of measurements (online or offline), complexity, setup, calibration procedures, sampling tube design, measuring chamber and the way expiratory flow is controlled (Müller 2005). The stationary analysers measure FeNO by chemoluminescence whilst the portable FeNO analysers measure FeNO using electrochemistry.

How the intervention might work

As FeNO is reflective of airway eosinophilia in some circumstances, FeNO can be considered as a biomarker. For asthma, FeNO levels can potentially be used in children with asthma to:

- monitor airway eosinophilia;
- verify the adherence to ICS; and
- predict upcoming asthma exacerbations.

Reduction of airway inflammation improves symptoms and asthma control (Wardlaw 2000). Hence, the use of FeNO levels to tailor asthma medications in children with asthma may improve asthma control or reduce exacerbations, or both.

Why it is important to do this review

A previous Cochrane Review included both adults and children (Petsky 2009). Given the clinical heterogeneity between children and adults with asthma, rather than update that review, we undertook separate reviews for children and adults. This review focuses on children and there is a similar systematic review that includes only adults (Petsky 2016).

A systematic review evaluating the efficacy of tailoring asthma interventions based on FeNO levels will be useful to guide clinical practice in children with asthma. Using FeNO routinely in clinical practice adds to the burden of asthma care and resource utilisation. In addition, routine use of FeNO to guide use of asthma medications may improve asthma control and reduce exacerbations and hospitalisations related to asthma.

Objectives

To evaluate the efficacy of tailoring asthma medications based on fractional exhaled nitric oxide (FeNO), in comparison to not using FeNO, that is, management based on clinical symptoms (with or without spirometry/peak flow) or asthma guidelines (or both), for asthma-related outcomes in children.

Methods
Criteria for considering studies for this review

Types of studies
We included randomised controlled trials (RCTs) comparing adjustment of asthma medications based on FeNO levels in comparison to those not using FeNO, that is, management based on clinical symptoms (with or without spirometry/peak flow) or current asthma guidelines, or both. We included studies reported as full-text, abstract only, and unpublished data.

Types of participants
We included children/adolescents with a diagnosis of asthma according to guideline-defined criteria. We excluded participants with the following comorbidities/characteristics: eosinophilic bronchitis, asthma related to an underlying lung disease such as bronchiectasis and chronic obstructive pulmonary disease or diagnostic categories such as ‘cough variant asthma’ and ‘wheezy bronchitis’.

Types of interventions
We included RCTs comparing adjustment of asthma medications based on FeNO levels versus control groups where FeNO is not used to adjust asthma medications. Control group interventions may have included use of clinical symptoms (with or without spirometry/peak flow) to guide adjustment of asthma medications. Studies that included the use of other interventions were included if all participants had equal access to such interventions. We included trials of at least 12 weeks’ duration.

Types of outcome measures

Primary outcomes
- Asthma exacerbations during follow-up defined as:
  - number of participants who had one or more exacerbation over the study period;
  - number of exacerbations per 52 weeks (exacerbation rate);
  - severe exacerbations requiring oral corticosteroids;
  - severe exacerbation requiring hospitalisations.

Secondary outcomes
- Objective measurements of asthma control (forced expiratory volume in one second (FEV₁), peak flow, airway hyper-responsiveness).
- FeNO level.
- Symptoms of asthma as reported in asthma QoL score.
- ICS dose at final visit.

Reporting one or more of the outcomes listed here was not an inclusion criteria for this review.

Search methods for identification of studies

Electronic searches
We identified studies from the Cochrane Airways Group’s Specialised Register (CAGR), which is maintained by the Information Specialist for the Group. The Register contains trial reports identified through systematic searches of bibliographic databases including the Cochrane Central Register of Controlled Trials (CENTRAL), MEDLINE, Embase, CINAHL, AMED and PsycINFO, and handsearching of respiratory journals and meeting abstracts (see Appendix 1 for further details). We searched all records in the CAGR using the search strategy in Appendix 2. We also conducted a search of ClinicalTrials.gov (www.ClinicalTrials.gov) and the World Health Organization (WHO) trials portal (www.who.int/ictrp/en/). We searched all databases from their inception to the present, and we imposed no restriction on language of publication. All searches were undertaken by the Cochrane Airways Group central team (by Elizabeth Stovold) and the latest search was undertaken on 30 June 2016.

Searching other resources
We checked reference lists of all primary studies and review articles for additional references. We searched relevant manufacturers’ websites for trial information. We searched for errata or retractions from included studies published in full-text on PubMed (www.ncbi.nlm.nih.gov/pubmed), and reported the date this was done within the review.

Data collection and analysis

Selection of studies
Two review authors (HP, KK) independently screened titles and abstracts for inclusion of all the potential studies we identified with the search and coded them as ‘retrieve’ (eligible or potentially eligible/unclear) or ‘do not retrieve’. We then retrieved the full-text study reports/publication and two review authors (HP, KK) independently screened the full-text and identified studies for inclusion, and identified and recorded reasons for exclusion of the ineligible studies. We planned to resolve any disagreement through discussion or, if required, consult a third review author (AC). We identified and excluded duplicates and collate multiple reports of the same study so that each study, rather than each report, was the unit of interest in the review. We recorded the selection process.
in sufficient detail to complete the PRISMA flow diagram and Characteristics of excluded studies table.

Data extraction and management
We used a data collection form for study characteristics and outcome data which was piloted on at least one study in the review. One review author (HP) extracted study characteristics from included studies. A second review author (KK) spot-checked study characteristics for accuracy against the trial report. We then extracted the following study characteristics.

- Methods: study design, total duration of study, details of any 'run-in' period, number of study centres and location, study setting, withdrawals and date of study.
- Participants: number, mean age, age range, gender, severity of condition, diagnostic criteria, baseline lung function, smoking history, inclusion criteria and exclusion criteria.
- Interventions: intervention, comparison, concomitant medications and excluded medications.
- Outcomes: primary and secondary outcomes specified and collected, and time points reported.
- Notes: funding for trial, and notable conflicts of interest of trial authors.

Two review authors (HP, KK) independently extracted outcome data from included studies from current search. We noted in the Characteristics of included studies table if outcome data were not reported in a usable way. We resolved disagreements by consensus or by involving a third review author (AC). One review author (HP) transferred data into Review Manager 5 (RevMan 2014). We double-checked that data were entered correctly by comparing the data presented in the systematic review with the study reports.

Assessment of risk of bias in included studies
Two review authors (HP, KK) independently assessed risk of bias for each new study using the criteria outlined in the Cochrane Handbook for Systematic Reviews of Interventions (Higgins 2011). We planned to resolve any disagreements by discussion or by involving another review author (AC). We assessed the risk of bias according to the following domains.

- Random sequence generation.
- Allocation concealment.
- Blinding of participants and personnel.
- Blinding of outcome assessment.
- Incomplete outcome data.
- Selective outcome reporting.
- Other bias.

We graded each potential source of bias as high, low or unclear and provided a quote from the study report together with a justification for our judgement in the 'Risk of bias' table. We then summarised the risk of bias judgements across different studies for each of the domains listed. We planned to blind separately for different key outcomes where necessary (e.g. for unblinded outcome assessment, risk of bias for all-cause mortality may be very different from for a participant-reported pain scale). Where information on risk of bias related to unpublished data or correspondence with a trialist, we noted this in the 'Risk of bias' table. When considering treatment effects, we considered the risk of bias for the studies that contributed to that outcome.

Assessment of bias in conducting the systematic review
We conducted the review according to the published protocol and reported any deviations from it in the Differences between protocol and review section of the systematic review.

Measures of treatment effect
We analysed dichotomous data as odds ratios (OR) and continuous data as mean difference (MD) or standardised mean difference (SMD) with 95% confidence intervals (CI). We then entered data presented as a scale with a consistent direction of effect. We undertook meta-analyses only where it was meaningful (i.e. if the treatments, participants and the underlying clinical question were similar enough for pooling to make sense). We narratively described skewed data reported as medians and interquartile ranges.

Where multiple trial arms were reported in a single trial, we included only the relevant arms. If two comparisons (e.g. drug A versus placebo and drug B versus placebo) were combined in the same meta-analysis, we halved the control group to avoid double-counting.

Unit of analysis issues
For dichotomous data, we reported the proportion of participants contributing to each outcome in comparison with the total number randomised. For rate ratios of common events whereby one participant may have more than one event, we used generic inverse variance (GIV) analysis. The rate ratios were taken from the published papers and the standard errors calculated from CIs or P values published in the papers. We had planned for cross-over studies, to calculate the mean treatment differences from raw data, and variances extracted or imputed and entered as a fixed-effect (GIV) outcome, to provide summary weighted differences and 95% CIs.

Dealing with missing data
We contacted investigators or study sponsors to verify key study characteristics and obtain missing numerical outcome data where possible (e.g. when a study was identified as abstract only). Where
this was not possible, and the missing data were thought to introduce serious bias, we explored the impact of including such studies in the overall assessment of results by a sensitivity analysis.

**Assessment of heterogeneity**

We described any heterogeneity between the study results and tested it to see if it reached statistical significance using a Chi² test. We planned to include the 95% CI estimated using a random-effects model whenever there were concerns about statistical heterogeneity. Heterogeneity was considered significant when the P value is less than 0.10 (Higgins 2011). We then used the I² statistic to measure heterogeneity among the trials in each analysis. If we identified substantial heterogeneity, we reported it and explored possible causes by prespecified subgroup analysis.

**Assessment of reporting biases**

We were unable to pool more than 10 trials, so did not create and examine a funnel plot to explore possible small-study and publication biases.

**Data synthesis**

We included the results from studies that met the inclusion criteria and reported any of the outcomes of interest in the subsequent meta-analyses. We calculated the summary weighted RR and 95% CI (fixed-effect model) using Review Manager 5 (RevMan 2014). For rate ratios of common events whereby one participant may have more than one event, we used GIV. The rate ratios were taken from the published papers and the standard errors calculated from CIs or P values published in the papers. For cross-over studies, we planned to calculate the mean treatment differences from raw data, and extract or impute variances and enter them as fixed-effect GIV outcomes, to provide summary weighted differences and 95% CI. Numbers needed to treat were calculated from the pooled OR and its 95% CI applied to a specified baseline risk using an online calculator (Cates 2008). The outcome indices were assumed to be normally distributed continuous variables so the MDs in outcomes could be estimated. If studies reported outcomes using different measurement scales, we estimated the SMD.

**'Summary of findings' table**

We created a ‘Summary of findings’ table using the following outcomes:

- number of participants who had one or more exacerbations over the study period;
- number of asthma exacerbations per 52 weeks,
- ICS dose at final visit.

The ‘Summary of findings’ table in the previous combined review (Petsky 2009) was amended to reflect new data and restricted to the inclusion criteria. We used the five GRADE considerations (study limitations, consistency of effect, imprecision, indirectness and publication bias) to assess the quality of a body of evidence as it relates to the studies which contribute data to the meta-analyses for the prespecified outcomes. We then used methods and recommendations described in Section 8.5 and Chapter 12 of the Cochrane Handbook for Systematic Reviews of Interventions (Higgins 2011) using GRADEpro software (GRADEpro GDT 2015). We justified all decisions to downgrade or upgrade the quality of studies using footnotes and we made comments to aid reader’s understanding of the review where necessary.

**Subgroup analysis and investigation of heterogeneity**

We planned the following subgroup analyses:

- basis for adjustment of ICS in the control group (guideline driven monitoring versus non-guideline driven);
- use of spirometry or peak flow as an adjunctive monitoring tool for adjustment of medications versus non-use of spirometry or peak flow;
- baseline ICS dose at commencement of intervention (low-medium (< 800 µg/day of budesonide equivalent) versus high dose (800 µg/day or more of budesonide equivalent);
- FeNO cut-offs for adjustment of medications (20 parts per billion (ppb) or less versus more than 20 ppb);
- FeNO cut-offs, based on presence of atopy.

**Sensitivity analysis**

We carried out the following sensitivity analyses.

- Sensitivity analysis excluding studies with a high risk of bias based on the ‘Risk of bias’ assessment. We removed studies that did not have adequate allocation concealment and sequence generation.
- Variation in the inclusion criteria. We removed studies that included children not receiving ICS at recruitment.
- Differences in the medications used in the intervention and comparison group. We removed studies that adjusted medications only for one arm.
- Analysis comparing the random-effects model to a fixed-effect model.
- Analysis by ‘strategy received’. We removed studies with hierarchy management protocols that only considered use of steroids for each step (i.e. without consideration for using montelukast or long-acting beta-agonist (LABA), or both, at any point).

**RESULTS**

**Description of studies**
See: Characteristics of included studies; Characteristics of excluded studies; Characteristics of ongoing studies tables.

**Results of the search**

From the searches, the CAGR identified 1084 potentially relevant titles (Figure 1). We identified an additional 129 titles through searches of ClinicalTrials.gov (www.ClinicalTrials.gov) and the WHO trials portal (www.who.int/ictrp/en/). After assessing the abstracts, we obtained 30 papers for consideration after removing duplicates. We excluded 14 papers due to non-randomisation or treatment not being based on FeNO. Of the potential 16 papers, nine included children or adolescents and the remaining seven were based on adults, which are presented in a separate Cochrane Review (Petsky 2016).
Figure 1. Prisma flow diagram.
 Included studies

The review included nine studies (see Characteristics of included studies). The nine studies involved 1426 randomised participants with 1329 completing the trials (Pijnenburg 2005; Fritsch 2006; Szefler 2008; de Jongste 2008; Verini 2010; Pike 2013; Peirsman 2014; Petsky 2015; Voorend-van Bergen 2015). Of these nine studies, five were new (i.e. were not in the previous (Petsky 2009) review).

 Study design

All nine studies were parallel-group studies. Five were multicentre studies (Szefler 2008; de Jongste 2008; Pike 2013; Peirsman 2014; Voorend-van Bergen 2015), one was dual centre (Petsky 2015), and three were single-centre studies (Pijnenburg 2005; Fritsch 2006; Verini 2010). One study used a three-arm strategy to adjust ICS (Voorend-van Bergen 2015). The strategy arms were: web group, where treatment was adjusted monthly based on the web-based Asthma Control Test (ACT) score; FeNO group, where treatment was adjusted according to FeNO and ACT score at four-monthly clinic visits; or standard care, where treatment was adjusted according to the ACT score during clinic visits. For this review, we considered the FeNO with ACT score strategy arm as the intervention group and the standard care strategy as the control group. Of the nine studies; four were double blind (Pijnenburg 2005; Szefler 2008; Pike 2013; Petsky 2015), three were single blind (Fritsch 2006; Peirsman 2014; Voorend-van Bergen 2015), and two had no blinding (de Jongste 2008; Verini 2010). The study duration varied ranging from 6 to 12 months (Table 1). Each study defined exacerbations differently (Table 1).

 Participants

The nine studies had different inclusion criteria for the participants. All studies included participants with asthma which was defined as per current guidelines.

 Fractional exhaled nitric oxide strategy

The intervention arm in all nine studies, although primarily based on FeNO level, differed in the cut-off for FeNO for change in therapy. Petsky 2015 was the only study which utilised different cut-offs for the presence of atopy. The FeNO cut-offs used for the studies are presented in Table 1.

 Control group

Five of the nine studies utilised existing asthma guidelines to adjust treatment in the control group (Fritsch 2006; Szefler 2008; Verini 2010; Pike 2013; Peirsman 2014). Three studies used participant-reported symptoms (Pijnenburg 2005; de Jongste 2008; Petsky 2015), and one utilised the Asthma Control Questionnaire (ACQ) (Voorend-van Bergen 2015). The control group strategies are described in Table 1.

 Outcomes

The primary outcomes of the studies also varied. Three studies used symptom-free days (de Jongste 2008; Peirsman 2014; Voorend-van Bergen 2015), three studies used asthma exacerbations (Verini 2010; Pike 2013; Petsky 2015), three studies included ICS cumulative doses (Pijnenburg 2005; Verini 2010; Pike 2013), one study used number of days with symptoms (Szefler 2008), and another used FEV1 (Fritsch 2006). The definitions of exacerbations were different among the studies (Table 1).

 The secondary outcomes also varied between the studies. Four studies included asthma exacerbations (Fritsch 2006; Pike 2013; Peirsman 2014; Voorend-van Bergen 2015), four studies used dose of ICS (Fritsch 2006; de Jongste 2008; Petsky 2015; Voorend-van Bergen 2015), three studies included spirometry (de Jongste 2008; Petsky 2015; Voorend-van Bergen 2015), and Petsky 2015 and de Jongste 2008 used asthma QoL questionnaires. We contacted study authors to request further data, or data that could be included in the meta-analysis; three study authors provided data (Pike 2013; Petsky 2015; Voorend-van Bergen 2015). The study characteristics are described in the Characteristics of included studies table.

 Excluded studies

We recorded the reasons for excluding the 20 studies in the Characteristics of excluded studies table. The most common reasons for exclusion were: not an RCT (seven studies), treatment not adjusted according to FeNO (six studies), and population was not children or adolescents (seven studies). One further study was found in abstract format only (Duong-Quy 2015). We contacted this study author in January 2016 and they confirmed that the paper is in preparation, therefore this study was judged to be ongoing and will be included in the next update (Duong-Quy 2015).

 Risk of bias in included studies

The full details of risk of bias judgements is described under the ‘Risk of Bias’ section in the Characteristics of included studies table and is summarised in Figure 2. Overall, the methodological quality of the included studies was good.
Figure 2. Risk of bias summary: review authors' judgements about each risk of bias item for each included study.
Allocation
Four studies described generation of randomisation sequence (Szefler 2008; Pike 2013; Petsky 2015; Voorend-van Bergen 2015), and it was unclear in five studies (Pijnenburg 2005; Fritsch 2006; de Jongste 2008; Verini 2010; Peirsman 2014). The method of allocation concealment was adequate in four studies (Szefler 2008; Pike 2013; Peirsman 2014; Petsky 2015), and unclear in five (Pijnenburg 2005; Fritsch 2006; de Jongste 2008; Verini 2010; Voorend-van Bergen 2015).

Blinding
Risk associated with participant blinding was low when the blinding of assessors was based on information provided by authors of the studies. These included comments from the studies such as "a third party provided advice on treatment decisions" and "both arms of the study received the same follow-up including measurements and tests".

Incomplete outcome data
Five studies were at low risk of attrition bias (Szefler 2008; de Jongste 2008; Peirsman 2014; Petsky 2015; Voorend-van Bergen 2015). Three studies were at high risk of attrition bias as they reported unbalanced dropout rates (Fritsch 2006; Pijnenburg 2005; Pike 2013). Verini 2010 did not report on dropouts and was therefore judged at unclear risk of attrition bias.

Selective reporting
Reporting bias was low in two studies with all outcomes being reported (Peirsman 2014; Voorend-van Bergen 2015). Three studies were at unclear risk of reporting bias as there was inadequate information in the published articles (Pijnenburg 2005; de Jongste 2008; Pike 2013). Four studies were at high risk of reporting bias as some of the secondary outcomes were not reported or incorrect analyses methods were used (Fritsch 2006; Szefler 2008; Verini 2010; Petsky 2015).

Other potential sources of bias
Another source of bias was the success of obtaining FeNO levels at each visit according to current guidelines. Five studies did not report the success of obtaining FeNO at each time point (Pijnenburg 2005; Szefler 2008; Verini 2010; Peirsman 2014; Voorend-van Bergen 2015). One study reported that they successfully obtained FeNO at each visit (Petsky 2015). Two studies were at high risk as they reported technical problems with the FeNO analysers including 11 out of 77 analysers showing drift in calibration after the study (Fritsch 2006; de Jongste 2008). Pike 2013 was at high risk as they reported not following current guidelines by only doing a single measurement of FeNO at each visit.

Effects of interventions
See: Summary of findings for the main comparison Tailoring asthma treatment using fractional exhaled nitric oxide versus clinical symptoms
See Summary of findings for the main comparison for the main comparisons.

Primary outcome: asthma exacerbations
Three studies used asthma exacerbations as their primary outcome but the definition differed among the studies (described in Table 1), as did the way the outcome was measured and presented (Verini 2010; Pike 2013; Petsky 2015). Three studies reported a reduction in asthma exacerbations in the intervention arm compared to the control arm (Verini 2010; Peirsman 2014; Petsky 2015). For the various types of exacerbations, we combined data into the meta-analysis, as described below.

1.1 Number of participants who had one or more exacerbations over the study period
See Analysis 1.1.
Combined data from eight studies showed that the number of participants experiencing an exacerbation was significantly lower (P = 0.0002) in the FeNO group compared to the control (clinical symptom) group over the study period (OR 0.58, 95% CI 0.45 to 0.75; 1279 participants; 8 studies; I² = 7%) (de Jongste 2008; Peirsman 2014; Petsky 2015; Pijnenburg 2005; Pike 2013; Szefler 2008; Verini 2010; Voorend-van Bergen 2015). There was some statistical heterogeneity among the studies but it was not significant (I² = 7%). In the control group where therapy was guided according to clinical symptoms, 40 children out of 100 had at least one exacerbation over 48.5 weeks, compared to 28 (95% CI 23 to 33) out of 100 for those where treatment was guided by FeNO. The number needed to treat to show an additional beneficial outcome (NNTB) over 52 weeks was 9 (95% CI 6 to 15) (Figure 3).
Figure 3. In the control group, 40 children out of 100 had exacerbations over one year, compared to 28 (95% confidence interval (CI) 23 to 33) out of 100 for the active treatment group. Number needed to treat for one additional beneficial outcome = 9 (95% CI 6 to 15).

1.2 Number of exacerbations per 52 weeks (exacerbation rates)

See Analysis 1.2.

Combined data from four studies for the outcome of exacerbation rate (over 52 weeks) found no differences between the groups (P = 0.09) (MD -0.37, 95% CI -0.80 to 0.06; 736 participants; 4 studies) (Szefler 2008; Verini 2010; Pike 2013; Petsky 2015). As there was statistical heterogeneity among the studies (I² = 67%, P = 0.03), we used a random-effects analysis. The statistical heterogeneity could be accounted for by the skew in some of the studies data. The rate of exacerbation over the 52 weeks in the control group ranged from 0.78 to 3.2.

1.3 Number of participants who had severe exacerbations requiring hospitalisation

See Analysis 1.3.

Five studies reported hospitalisations due to worsening of asthma symptoms (Fritsch 2006; Szefler 2008; Pike 2013; Peirsman 2014; Voorend-van Bergen 2015), and another study reported that no participants were hospitalised (Petsky 2015). In the meta-analysis, there was no significant difference (P = 0.37) between groups; 20 children in the FeNO group versus 26 in the control group required hospitalisation (OR 0.75, 95% CI 0.41 to 1.36; 1110 participants; 6 studies; I² = 0%).

1.4 Number of participants who had severe exacerbations requiring rescue oral corticosteroids

See Analysis 1.4.

Seven studies reported using rescue oral corticosteroids (de Jongste 2008; Fritsch 2006; Peirsman 2014; Petsky 2015; Pijnenburg 2005; Szefler 2008; Voorend-van Bergen 2015). The meta-analysis showed a significantly fewer children (P = 0.001) in the FeNO group required rescue oral corticosteroids compared to the control group.
control group (OR 0.63, 95% CI 0.48 to 0.83; 1169 participants; 7 studies; \( I^2 = 0\% \)).

**Secondary outcomes**

1.5 FEV\(_1\) % predicted at final visit

See Analysis 1.5.

We combined the final visit FEV\(_1\) % predicted from seven studies in a meta-analysis and we found no significant difference between the groups (\( P = 0.12; \) MD 1.0, 95% CI -0.07 to 2.07; 1181 participants; 7 studies; \( I^2 = 0\% \)) (de Jongste 2008; Peirsman 2014; Petsky 2015; Pijnenburg 2005; Pike 2013; Szefler 2008; Voorend-van Bergen 2015). The two remaining studies reported no significant difference between the two groups, but as details were not provided, we could not include the data in the meta-analysis (Fritsch 2006; Verini 2010).

1.6 FeNO geometric mean level at final visit

See Analysis 1.6.

We combined the final visit’s FeNO geometric mean (GM) from three studies in a meta-analysis (de Jongste 2008; Pijnenburg 2005; Voorend-van Bergen 2015). The data were heavily skewed and ratio of GM was the most appropriate analysis to use. There was no significant difference between the groups (GM 0.98, 95% CI 0.87 to 1.11; 356 participants; 3 studies; \( I^2 = 69\% \)). The remaining six studies could not be included in the meta-analysis but reported that there was no significant difference between the groups at the final visit (Fritsch 2006; Peirsman 2014; Petsky 2015; Pike 2013; Szefler 2008; Verini 2010). Fritsch 2006, and Peirsman 2014 reported that there was a decreased trend in FeNO levels for the FeNO group at the final visit but this was not significant.

1.7 Symptom score: Asthma Control Test

See Analysis 1.7.

Two studies reported ACT results; the meta-analysis showed no significant difference between groups (MD 0.14, 95% CI -0.18 to 0.47; 724 participants; 2 studies; \( I^2 = 62\% \)) (Szefler 2008; Voorend-van Bergen 2015).

1.8 Symptom score as per Paediatric Asthma Caregiver’s Quality of Life Questionnaire (PACQLQ)

See Analysis 1.8.

Combined data from three studies found no significant difference between groups for the PACQLQ (MD 0.09, 95% CI -0.08 to 0.27; 380 participants; 3 studies; \( I^2 = 0\% \)) (de Jongste 2008; Petsky 2015; Voorend-van Bergen 2015).

1.9 Inhaled corticosteroid dose at final visit (budesonide equivalent in micrograms per day)

See Analysis 1.9.

Three studies reported final ICS doses that could be included in a meta-analysis; there was no significant difference between the groups (MD 63.95 \( \mu \)g/day, 95% CI -51.89 to 179.79; 317 participants; 3 studies; \( I^2 = 40\% \)) (Pike 2013; Petsky 2015; Voorend-van Bergen 2015). Using a random-effects model, the difference between the groups remained nonsignificant (MD 65.88 \( \mu \)g/day, 95% CI -86.71 to 218.47).

Four studies reported that there was no difference in daily ICS doses between the groups at the final visit (Pijnenburg 2005; de Jongste 2008; Verini 2010; Peirsman 2014). The remaining two studies reported that the control group had lower doses of ICS at the end of the study (Fritsch 2006; Szefler 2008).

1.10 Cost effectiveness of the intervention

One study (Voorend-van Bergen 2015) published a separate paper (Beerthuizen 2016) assessed the cost of the strategies in their three-armed trial (standard care, web-based strategy and FeNO-based). They reported no significant difference in costs or quality-adjusted life years between the groups. The web-based strategy (this arm not included in this systematic review) was 77% more cost effective from a healthcare perspective, whereas the FeNO-based strategy had an 83% chance of being most cost effective from a societal perspective.

Subgroup analysis and investigation of heterogeneity

1. Based on adjustment of inhaled corticosteroid in the control group (guideline-driven versus others)

When testing for subgroup differences there was no significant difference between the subgroups for either exacerbation outcome (Analysis 1.10; Analysis 1.11). Four of the studies utilised asthma guidelines as the basis of adjusting medications in the control group (Szefler 2008; Verini 2010; Pike 2013; Peirsman 2014). In this subgroup, for the primary outcome of number of participants with one or more exacerbations, the significant difference between the groups was still present, favouring the FeNO group (OR 0.67, 95% CI 0.51 to 0.90). In the studies that used other methods for adjusting medications as the control group, also fewer children in the FeNO group had exacerbations compared to the control group (OR 0.55, 95% CI 0.34 to 0.90). Likewise, there was a significant difference between the groups for the outcome of exacerbation rates for the studies where the control groups’ management was guideline-driven (MD -0.27, 95% CI -0.49 to -0.06), as well as for the studies where the control groups’ management was not guideline-driven (i.e. other)
(MD -0.39, 95% CI -0.84 to 0.06). However, there was significant statistical heterogeneity in this subgroup analyses when considering only the guideline-driven studies.

2. Use of spirometry or peak flow as an adjunctive monitoring tool for adjustment of medications (versus non-use of spirometry or peak flow)

Five studies utilised spirometry when adjusting medications in the control group (Fritsch 2006; Szefler 2008; Verini 2010; Pike 2013; Peirsman 2014); however, spirometry was not the sole measurement for adjusting the medications, therefore this subgroup analysis could not be done. As per Table 1, all five studies used asthma guidelines which included participant-reported symptoms, SABA use and spirometry.

3. Baseline inhaled corticosteroid dose at commencement of intervention (low-medium (< 800 µg/day of budesonide equivalent) versus high dose (800 µg/day or more of budesonide equivalent))

In six studies, the median ICS dose at baseline was less than 800 µg/day of budesonide equivalent (Pijnenburg 2005; Fritsch 2006; de Jongste 2008; Peirsman 2013; Petsky 2005; Voorend-van Bergen 2015). However, none of the studies analysed their data based on baseline ICS dose, hence this subgroup analysis could not be done.

One study did not provide the daily ICS dosage in micrograms per day so could not be included in this subgroup analysis (Verini 2010).

4. Fractional exhaled nitric oxide cut-offs for adjustment of medications (20 ppb or less versus more than 20 ppb)

Three studies adjusted medications when the FeNO levels were 20 ppb or less as described in Table 1 (Fritsch 2006; Verini 2010; Petsky 2015). When considering this in the subgroup analysis, the results were similar to the main analyses.

By removing Pijnenburg 2005; Szeffler 2008; de Jongste 2008; Pike 2013; Peirsman 2014; and Voorend-van Bergen 2015 (in Analysis 1.1) who adjusted medications when FeNO was greater than 20 ppb from the first outcome (number of participants who had one or more exacerbations), the difference between groups remained statistically different (P = 0.0007; OR 0.25, 95% CI 0.11 to 0.56; I² = 0%). Likewise, for the second outcome of exacerbation rates, by removing Szeffler 2008 and Pike 2013, the difference between groups favoured the FeNO group (MD -0.63, 95% CI -0.98 to -0.27; I² = 65%).

5. Fractional exhaled nitric oxide cut-offs, based on presence of atopy

Only one study considered atopy in their algorithm for FeNO levels (Petsky 2015). Removing this study from the primary outcomes of exacerbations, the meta-analyses results still significantly favoured the FeNO group. For the first outcome, the number of participants who had more than one exacerbation over the study period, the difference between groups remained statistically different (OR 0.65, 95% CI 0.51 to 0.85; I² = 9%). Likewise, for the exacerbation rates, removing Petsky 2015 from the FeNO group also resulted in a statistically difference between groups (MD -0.27, 95% CI -0.49 to -0.06; I² = 77%).

Sensitivity analyses

1. Excluding studies with a high risk of bias based on the ‘Risk of bias’ assessment

There were three included studies which had no blinding (de Jongste 2008; Verini 2010; Voorend-van Bergen 2015). However, when the data from these studies was removed it did not alter the results of the primary outcome (exacerbations) found in the main analyses. Summary data for the number of participants who had one or more exacerbations over the study period (OR 0.67, 95% CI 0.50 to 0.89; 887 participants; 5 studies) and exacerbation rate (MD -0.2, 95% CI -0.41 to 0.0; 672 participants; 3 studies) still favoured the FeNO group.

2. Variation in the inclusion criteria

Three studies reported that not all included children were receiving ICS at recruitment (Fritsch 2006; Verini 2010; Pike 2013). Removing Verini 2010 and Pike 2013 from the analyses resulted in similar results (i.e. outcomes favoured the FeNO group); the number of participants who had one or more exacerbations (OR 0.64, 95% CI 0.49 to 0.84; 1125 participants; 6 studies). Likewise, the group differences for exacerbation rate remained significantly different between groups favouring the FeNO group (MD -0.23, 95% CI -0.43 to -0.02; 609 participants; 2 studies).

3. Differences in the medications used in the intervention and comparison group

There were no studies that adjusted medications only for one arm, therefore this planned sensitivity analysis was not undertaken.

4. Analysis using random-effects model

Using a random-effects model did not change the significant group differences between the groups (i.e. favoured the FeNO group), in the number of participants who had one or more exacerbations over the study period (OR 0.58, 95% CI 0.42 to 0.81; 1279 participants; 8 studies).
Due to the high levels of heterogeneity ($I^2 = 67\%$), we used a random-effects model to analyse number of exacerbations per 52 weeks, which resulted in a non-statistically significant estimate favouring the FeNO group (MD $-0.37$, 95% CI $-0.80$ to $0.06$; 736 participants; 4 studies). There was a significant difference between groups when a fixed-effect model was applied (MD $-0.30$, 95% CI $-0.49$ to $-0.10$; 736 participants; 4 studies), but this latter model is considered less appropriate in the context of high levels of heterogeneity.

5. Analysis by 'strategy received'

One study used a hierarchy management protocol that was based solely on the use of steroids for each step (i.e. without consideration for using montelukast or LABA, or both, at any point) (Pijnenburg 2005). Removing this study from the analyses did not alter the significant group differences found in the main analyses. The number of participants who had one or more exacerbations over the study period favoured the FeNO arm (OR $0.62$, 95% CI $0.48$ to $0.8$; 1190 participants; 7 studies).

**DISCUSSION**

**Summary of main results**

The nine RCTs included in this review involved 1426 children (1329 completed). The studies varied in many aspects including the FeNO levels used, the algorithms, study duration and the strategy used for the control arm.

All studies reported our review’s primary outcome (exacerbation). However, the studies defined exacerbation in various ways. Data from eight studies were combined for the meta-analysis of the outcome, number of participants having one or more asthma exacerbation. Significantly fewer children in the FeNO group had exacerbations compared to the control group (OR $0.58$, 95% CI $0.45$ to $0.75$). The NNNT over 52 weeks was 9 (95% CI 6 to 15). There was no difference between the groups when comparing the exacerbation rates (MD $-0.37$, 95% CI $-0.8$ to $0.06$). When combining seven studies, we found that fewer children in the FeNO group required rescue courses of oral corticosteroids compared to controls (OR $0.63$, 95% CI $0.48$ to $0.83$). However, there was no difference between the groups for severe exacerbations requiring hospitalisation (OR $0.75$, 95% CI $0.41$ to $1.4$). There were 20 hospitalisations in the FeNO group versus 26 in the control group. In the subgroup analyses, the main analyses for the primary outcome of exacerbations continued to favour the FeNO group when restricting the analysis to the studies that utilised guidelines for the control group (number of participants who had one or more exacerbation: OR $0.67$, 95% CI $0.51$ to $0.90$; exacerbation rate: MD $-0.27$, 95% CI $0.49$ to $-0.06$). There was no statistical difference between the subgroups in these analyses.

In the sensitivity analyses, the only changes seen in the primary outcome analyses was when we applied the fixed-effect analysis to the outcome exacerbation rates per 52 weeks. As per our protocol, we chose to perform our primary analysis of this outcome with a random-effects model, which is more appropriate in the context of the substantial heterogeneity detected ($I^2 = 67\%$). Unlike the random-effects model, the fixed-effect model resulted in a statistically significant estimate favouring the FeNO group (MD $-0.30$, 95% CI $-0.49$ to $-0.10$; 736 participants; 4 studies). However, the number of participants who had one or more exacerbation over the study period (analysed primarily with a fixed-effect model) remained favourable towards the FeNO group when a sensitivity analysis was performed with a random-effects model (OR $0.58$, 95% CI $0.42$ to $0.81$).

In contrast to the data relating to exacerbations, there was no significant difference between groups for any of the secondary outcomes (FEV$_1$, FeNO levels, symptom scores or final ICS dose).

**Overall completeness and applicability of evidence**

This review included nine studies but not all studies could be included in every outcome for the meta-analyses. The meta-analyses consisted of data from two to eight studies. The number of children for the various outcomes ranged from 317 (outcome: ICS dose at final visit) to 1297 (outcome: Number of participants who had one or more exacerbations over the study period). Therefore, the completeness of the review was limited by the available data, although we contacted the authors of the included studies for additional data.

Two of the primary outcomes (‘Number of participants who had one or more exacerbations over the study period’ and ‘Severe exacerbations requiring oral corticosteroids’) favoured the FeNO arm, however there was no significant group differences for ‘Exacerbation rate’, ‘Severe exacerbations requiring hospitalisation’ or for any secondary outcomes (symptom scores, FeNO at end of study, FEV$_1$ at end of study or ICS doses). There were no changes in the primary outcomes when subgroup analysis was undertaken with FeNO group being favoured in three out of four of the primary analyses.

All nine studies were hospital-based and undertaken since the early 2000’s in affluent countries; three in the Netherlands (Pijnenburg 2005; de Jongste 2008; Voorend-van Bergen 2015), one in Austria (Fritsch 2006), one in Belgium (Peirsmans 2014), one in Australia (Potsky 2015), one in the UK (Pike 2013), one in the USA (Szeffler 2008), and one in Italy (Verini 2010). There is a gap of evidence from the low-income countries, therefore limiting this review’s findings in resource-poor settings. Likewise, none of the included studies were from a primary care setting, therefore restricting interpretation of these findings to hospital settings only. As children looked after in primary care are likely to have less severe asthma (compared to children looked after in hospitals).
Guidelines on the interpretation of FeNO levels suggest using a cut-off of less than 20 ppb as normal and more than 35 ppb as reflective of the presence of inflammation in children (Dweik 2011). However, it remains unknown how other significant influences of FeNO should be considered. These influences include ethnicity (ATS 2005) and atopy (Petsky 2015). Further, the FeNO cut-off values used to adjust the medications varied among the studies although it could be argued that the cut-off used should be individualised with each child having their own baseline FeNO value. None of the studies used this approach. Thus, it remains unknown how best to use FeNO values.

Also, as FeNO levels reflect airway eosinophilia in steroid-naive people, the results of the review are unlikely to apply to those children with non-eosinophilic asthma.

In our review, there was a discordance between the beneficial effect of using FeNO to guide asthma therapy for exacerbations compared to other clinically important outcomes such as QoL, asthma control and lung function. One possible reason relates to a type-1 error (insufficient sample size). However, 724 participants used the ACQ and 380 participants used the PACQLQ. Thus, it is unlikely that there was a type-1 error present.

Lastly, none of the studies included in this review undertook a cost analyses and its absence limits the applicability in ‘real-life’ clinical practice.

Quality of the evidence

The ‘Summary of findings’ table summarises the evidence for the three main outcomes relating to exacerbations and ICS dose. Overall the quality of evidence was very low to moderate using the GRADE system. As two studies were not blinded (de Jongste 2008; Verini 2010) and another (Voorend-van Bergen 2015) was single blinded this reduced our confidence in these studies as they introduced bias. Removing these studies for the sensitivity analysis, still showed a reduction in the number of exacerbations in the FeNO group. However, we downgraded the evidence using GRADE to moderate as displayed in Summary of findings for the main comparison.

We downgraded the outcome of exacerbation rate to very low due to the statistical heterogeneity ($I^2 = 67\%$, P = 0.03), imprecision and risk of bias. The fact that a random-effects model showed no difference between the groups, whereas a fixed-effect model did show a difference, demonstrates the imprecision and potential skew of the data. The study that likely contributed to the statistical heterogeneity was that of Pike 2013 who stated that their data for exacerbation rates was skewed when they provided further data to us. Consequently, they reported their published data as medians and interquartile ranges.

Potential biases in the review process

We are unaware of any biases in the review process. We used a comprehensive search strategy and adhered to the protocol. Two review authors (HP, KK) independently assessed the risk of bias. We contacted the corresponding authors of all the studies for raw data to include in the meta-analysis. One review author and the review editor (Christopher Cates) independently checked data extraction, risk of bias assessment and downgrading decisions for the ‘Summary of findings’ tables to minimise the risk of bias in the review process.

As two of the review authors (HP, AC) conducted one of the studies included in this review (Petsky 2015), a separate review author (KK) made final decisions on this paper’s risk of bias.

Agreements and disagreements with other studies or reviews

This review updated a previous Cochrane Review (Petsky 2009), which included studies involving children and adults. The decision was to separate the review based on population ages and the increased clinical trials on the subject. The original review included two adult studies and four paediatric studies involving 1010 participants (Petsky 2009). This paediatric review includes nine studies with 1329 children completing. A separate systematic review on adults includes seven studies with 1546 participants completing (Petsky 2016). The review in adults found similar results to this paediatric review.

Results from the original review (Petsky 2009) were different to those of this current review. The old review found no significant difference between the groups for the primary outcome of exacerbations. The four paediatric papers included in the original review reported that the FeNO group experienced fewer exacerbations in comparison to the control group, but the difference was not significant ($P = 0.06$) when combining three studies in a meta-analysis (OR 0.75, 95% CI 0.55 to 1.01) (Pijnenburg 2005; Fritsch 2006; Szeffler 2008; de Jongste 2008). However, combining the data from eight studies in this review showed that the number of participants experiencing an exacerbation was significantly lower ($P = 0.0002$) in the FeNO group compared to the control group (OR 0.62, 95% CI 0.49 to 0.80) (Pijnenburg 2005; Szeffler 2008; de Jongste 2008; Verini 2010; Pike 2013; Peirsman 2014; Petsky 2015; Voorend-van Bergen 2015). There was no heterogeneity between the studies ($I^2 = 21\%$).

Lu 2015 completed a meta-analysis comparing the use of FeNO versus guideline-based management for children with asthma. They included six studies with 506 participants. Their results were similar to this Cochrane Review. Lu and coworkers described that significantly fewer participants in the FeNO group had exacerbations compared to the control group (more than one exacerbation: OR 0.69, 95% CI 0.53 to 0.90; $P = 0.005$). As with this Cochrane Review, Lu 2015 described no difference between groups for the outcomes of FeNO levels, FEV$_1$ or ICS dose.
Gomersal and colleagues conducted a systematic review but did not undertake a meta-analysis comparing FeNO-guided management with any other monitoring strategy for children with asthma (Gomersal 2016). Their review included seven studies and the authors stated that there was a “trend towards reduced exacerbation and increased medications use” in the FeNO group. Furthermore, they identified issues with heterogeneity between the algorithms and included cohorts. They concluded that the benefits of utilising FeNO monitoring in children with asthma remains ambiguous. There are no guidelines currently that recommend the use of FeNO routinely in monitoring asthma. However, guidelines from the National Institute for Health and Care Excellence are currently focusing on the impact and feasibility of implementing FeNO in a diagnosis algorithm (NICE interim findings 2016).

Authors’ conclusions

Implications for practice

This review has demonstrated that tailoring asthma medications based on exhaled nitric oxide (FeNO) levels significantly reduces the number of children with one or more exacerbation (defined as any exacerbation or rescue oral corticosteroid courses but not hospitalisations) during the study period. However, use of the FeNO strategy was not beneficial for exacerbation rates, or the secondary outcomes of forced expiratory volume in one second (FEV1), FeNO levels, inhaled corticosteroid doses or symptom scores. Exacerbation rates were only significantly different between groups when the less appropriate fixed-effect model was applied to this outcome.

Acknowledgements

We thank Elizabeth Stovold for conducting the relevant searches.

We also thank the study authors who provided further data to allow inclusion of their data into the meta-analyses: Katy Pike, Marielle Pijnenburg (Voorend-van Bergen 2015).

We are grateful to Dr Christopher Cates, the Contact Editor for this review, who commented critically on the review and assisted in the data analyses.

The Background and Methods sections of this review are based on a standard template used by Cochrane Airways.

</thead>
<tbody>
<tr>
<td><strong>Methods</strong></td>
<td>Prospective, open-label, randomised, multicentre, parallel group study where ICS was adjusted every 3 weeks based on FeNO and symptom scores, or symptom scores alone. 4 randomised participants (2 in FeNO group, 2 in symptom group) were excluded from final results due to severe non-compliance (2), inappropriate inclusion (no allergy 1) and moving abroad (1). Study duration 30 weeks.</td>
</tr>
<tr>
<td><strong>Participants</strong></td>
<td>151 children randomised. FeNO group = 75: mean age 11.6 yrs (SD 2.6), 46 boys, 29 girls. Symptom group = 72: mean age 11.8 yrs (SD 4.3), 54 boys, 18 girls. Inclusion criteria: participants aged 6 to 18 yrs, stable mild-moderate asthma, diagnosed according to GINA guidelines, treatment with 200 µg to 1000 µg of inhaled budesonide or equivalent daily for 2 months prior to randomisation, and RAST class ≥ 2, or a positive SPT to ≥ 1 airborne allergen. Exclusion criteria: active smoking, previous admission to an ICU for asthma and concomitant disease that might affect FeNO.</td>
</tr>
<tr>
<td><strong>Interventions</strong></td>
<td>All participants scored asthma symptoms in an electronic diary over 30 weeks. FeNO group: participants received a portable FeNO analyser. Data were transmitted daily to the co-ordinating centres. Participants were telephoned every 3 weeks and their steroid dose was adapted according to FeNO and symptoms. Control group: participants were treated according to symptoms. Children were seen at 3, 12, 21 and 30 weeks for examination, assessment of FeNO, spirometry before and after salbutamol, and recording of adverse events.</td>
</tr>
<tr>
<td><strong>Outcomes</strong></td>
<td>Primary outcome: proportion of symptom-free days over the last 12 study weeks. Secondary outcomes: cumulative symptom scores, ICS dose as budesonide equivalent, FEV1 and reversibility, FeNO0.05, prednisone courses, emergency visits, hospitalisations for asthma and PACQLQ scores.</td>

## Methods
Randomised, single-blind, parallel study comparing asthma treatment adjusted based on GINA guidelines (clinical group) vs treatment guided by FeNO (FeNO group)
Participants had 5 visits (baseline, and months 3, 6, 9 and 12)
6 children did not complete the study (4 in clinical group, 2 in FeNO group)

## Participants
99 children randomised.
FeNO group: n = 49; mean age 10.6 yrs (SD 2.2), 33 boys, 16 girls
Clinical group: n = 50; mean age 10.7 yrs (SD 2.1), 33 boys, 17 girls
Children recruited from 7 Belgian hospitals.
Inclusion criteria: children with mild-to-severe asthma according to GINA guidelines for > 6 months and allergic sensitisation (i.e. positive SPT or specific IgE antibodies against inhalant allergens)
Exclusion criteria: significant comorbidity, acute asthma exacerbation or taken experimental medication 4 weeks prior to the screening visit, hospitalisation or systemic corticosteroids 12 weeks prior to screening visit (or both), or OCS dependency

## Interventions
FeNO group: treatment aimed to keep FeNO below 20 ppb.
Clinical group: treatment based on GINA guidelines (i.e. reporting of symptoms, need for rescue treatment in preceding 2 weeks and FEV<sub>1</sub>).

## Outcomes
Primary outcome: symptom-free days using first 4 questions from childhood ACT
Secondary outcomes: occurrence of exacerbations, unscheduled asthma-related contacts, hospital or emergency department admissions, non-attendance to school and career's work absence

## Notes
Study funded partially by Merck & Co and FeNO analysers supplied by Aerocrine but neither were involved in any part of the study

**Petsky 2015**

**Methods**

Randomised, double-blind, parallel study evaluated whether a treatment strategy based on FeNO levels, adjusted for atopy (FeNO group), in comparison to treatment strategy based on clinical symptoms (control group) could reduce asthma exacerbations Participants had 10 visits over 12 months (run-in, initial, months 1, 2, 3, 4, 6, 8, 10 and 12) 8 children did not complete the study (4 in FeNO group and 4 in control group)

**Participants**

FeNO group: n = 31, median age 10.17 yrs (IQR 6.56 to 12.69), 18 boys, 13 girls  
Symptom group: n = 32, median age 10.08 yrs (IQR 6.25 to 12.44), 13 boys, 19 girls  
Inclusion criteria: children aged > 4 yrs with persistent asthma, prescribed anti-inflammatory asthma treatment and receiving their care primarily through 2 hospitals (Brisbane and Hong Kong)  
Exclusion criteria: underlying cardio-respiratory illnesses such as bronchiectasis or tracheomalacia, inability to take ICS or LABA, or previous poor adherence to medications as documented in medical charts

**Interventions**

FeNO group: treatment adjusted on FeNO levels and atopic status  
Symptom group: treatment adjusted as recorded on asthma symptom diary card

**Outcomes**

Primary outcome: severe exacerbations defined as respiratory events requiring course of OCS with or without hospitalisation  
Secondary outcomes: FEV$_1$ % predicted, asthma QoL, symptom scores and dose of ICS at end of study (budesonide equivalent)

**Notes**

### Pijnenburg 2005

**Methods**  
Randomised, double-blind study evaluating whether titrating steroids on FeNO improved asthma management in children. Stratified by baseline FeNO (> 30 or < 30 ppb) and dose of ICS (> 400 µg/day or < 400 µg/day of budesonide or equivalent)  
Neither participants nor physicians were aware of which group they were randomised to  
7 dropouts: 3 during run-in, 3 from FeNO group (1 admitted to ICU) and 1 from symptom group  
Study duration 12 months, with 5 visits at 3-monthly intervals

**Participants**  
89 children randomised from 108 invited from outpatient clinic  
FeNO group n = 39: mean age 11.9 yrs (SD 2.9), 25 boys, 14 girls  
Symptom group n = 46: mean age 12.6 yrs (SD 2.8), 30 boys, 16 girls  
Inclusion: use of ICS at constant dose for at least 3 months preceding study. Atopy defined as RAST class ≥ 2 for at least 1 airborne allergen

**Interventions**  
Children were run-in for 2 weeks, then 3-monthly visits.  
FeNO group: FeNO-guided ICS dosing according to predetermined algorithm  
Symptom group: symptom scores influenced ICS dosing.

**Outcomes**  
Primary outcome: cumulative steroid dose (sum of mean daily steroid doses of visits 1 to 5)  
Secondary outcomes: mean daily symptom score, mean daily number of bronchodilator doses taken, % of symptom-free days during the last 4 weeks of the study, number of oral prednisone courses during the study, and provocative dose of methacholine causing a 20% fall in FEV1, FVC and MEF25 during final visit.

### Pike 2013

**Methods**

Randomised, double-blind, parallel-group trial. Participants were assigned to either FeNO-based or standard management strategy arms, and asthma treatment adjusted according to a predetermined algorithm. Participants and physicians not aware of their allocation. Study duration 12 months with study visits every 2 months. 13 children did not complete the study; 10 in FeNO group (8 withdrew, 1 non-adherence to protocol, 1 life-threatening exacerbation) and 3 withdrew in Standard management group.

**Participants**

90 children randomised from 96 screened. FeNO group n = 44: mean age 10.51 yrs (SD 2.62), 21 boys, 23 girls. Standard management group n = 46: mean age 11.42 yrs (SD 2.69), 30 boys, 16 girls. Inclusion criteria: aged 6 to 17 yrs, clinical diagnosis of asthma and treatment with beclomethasone dipropionate/budesonide ≥ 400 μg/day or fluticasone ≥ 200 μg/day. Asthma diagnosed upon a history of symptoms, ≥ 15% increase in FEV₁ with bronchodilator or diurnal PEF variability ≥ 15%.
Interventions | Participants needed to be stabilised prior to randomisation, then 2 monthly visits. FeNO group: FeNO measurements and symptom control. Standard management group: symptom control as per blinded clinician (reliever use, FEV₁).

Outcomes | Change in ICS dose, exacerbation frequency, FeNO measurements and lung function

### Methods
Randomised, double-blind, parallel-group trial. Participants had their asthma management based on standard treatment as per NAEPP guidelines or standard treatment modified based on measurements of FeNO. Participants and physicians were unaware of the treatment assignment. Study duration 46 weeks, with visits every 6 to 8 weeks. 12 randomised participants were lost to follow-up before the first outcome data were collected. During the 46-week follow-up, 17 participants in FeNO group dropped out and 23 in the control group.

### Participants
546 participants randomised from 780 children screened. FeNO group n = 276: mean age 14.4 yrs, 146 boys, 130 girls. Control group n = 270: mean age 14.4 yrs, 142 boys, 128 girls. Inclusion criteria: aged 12 to 20 yrs, diagnosed with asthma by their physician, symptoms of persistent asthma or evidence of uncontrolled disease as defined by NAEPP guidelines, and residents of urban census tracts in which at least 20% of households had incomes below the federal poverty threshold.

### Interventions
Run-in period of 3 weeks then scheduled visits every 6 to 8 weeks for 46 weeks. At each visit FeNO was measured, days of asthma symptoms assessed, use of rescue drugs, pulmonary function, use of health care, adherence to treatment regimen and missed days of school because of asthma. FeNO group: standard treatment modified based on measurements of FeNO. Control group: standard treatment based on the guidelines of NAEPP.

### Outcomes
Primary outcome: number of days with asthma symptoms. Secondary outcomes: admission to hospital, unscheduled visits to emergency departments or clinics, prednisone courses for asthma, asthma exacerbations, days of wheeze, days of interference with activities, nights of sleep deprivation, days of school or work missed, and days of interruption of guardian's activities.

Verini 2010

Methods
Randomised, open-label, parallel-group trial. Participants had their asthma treatment adjusted based on GINA guidelines (GINA group) or GINA guidelines and FeNO measurements (FeNO group)
Study duration 12 months with 3 visits (baseline, months 6 and 12)
All children completed the study.

Participants
FeNO group n = 32: mean age 10.7 yrs (SD 2.4), 18 boys, 14 girls
GINA group n = 32: mean age 11.3 yrs (SD 2.1), 18 boys, 14 girls
Inclusion criteria: all children had been admitted for allergic asthma and the diagnosis physician based according to ATS/ERS criteria

Interventions
Children reviewed 3 times over 12 months’ study duration.
At baseline and month 12 visits all children had clinical evaluation, allergy evaluation (SPT and IgE), lung function tests, FeNO measurement, diary card and asthma score therapy prior to randomisation
GINA group: at month 6 had diary card and clinical evaluation
FeNO group: at month 6 had diary card, clinical evaluation, lung function test, FeNO measurement and asthma score therapy
### Verini 2010 (Continued)

**Outcomes**

No clear definition given of outcomes, however asthma severity score, asthma exacerbation frequency and asthma therapy score were the main items reported in results section.

Voorend-van Bergen 2015

Methods

Multicentre, prospective, single-blind, parallel-group, 3-armed RCT. 2 monitoring strategies compared with standard care.

Web-based strategy used ACT to adjust treatment via a website at 1 monthly intervals.

FeNO-based strategy used FeNO and ACT.

Standard care strategy used ACT at 4 monthly visits.

The physicians were blinded to allocation, FeNO and ACT. Treatment plans were given to the physicians through local investigators based on the study algorithms.

Study duration 12 months with visits at 4 monthly intervals. 1 randomised participant from web-based group did not complete the 12-month follow-up.

Participants

272 children randomised from 481 screened.

Web-based group n = 91: mean age 10.6 yrs (SD 2.8), 60 boys, 31 girls

FeNO group n = 92: mean age 10.3 yrs (SD 2.9), 62 boys, 30 girls

Standard care group n = 89: mean age 10.2 yrs (SD 3.2), 61 boys, 28 girls

Inclusion criteria: aged 4 to 18 yrs, atopic asthma based on clinical symptoms, previous bronchodilator response > 9% increase in FEV1, previous airway hyper-responsiveness to methacholine.

Interventions

Run-in period of 4 weeks, then 4 monthly visits.

At each visit FeNO, ACT and diary was assessed. Additionally, at visit 1 and visit 4 FEV1 and PD20 were measured.

Web group: treatment modified by ACT and adherence.

FeNO group: treatment modified by ACT and FeNO.

Standard care group: treatment modified by ACT.

Outcomes

Primary outcome: changes from baseline of proportion of symptom-free days

Secondary outcomes: changes from baseline of ACT, daily symptom score, daily bronchodilator use, daily ICS dose, asthma-related QoL, dose of methacholine causing a 20% fall in FEV1 (PD20), FVC, FEV1 and MEF25 and exacerbations during the study.

Notes

We used the standard care strategy as the control group and did not consider the web-based strategy in this review.

“exhaled nitric oxide” AND “asthma” AND “clinical trials”

Contributions of Authors

All authors reviewed the manuscript.

HP and KK extracted the data and performed the analysis.

HP and AC wrote the manuscript.

Declarations of Interest

HP and AC: have conducted one RCT (Petsky 2015), which was one of the included studies in this review.

KK: none known.
SOURCES OF SUPPORT

Internal sources

• Children's Hospital Foundation, Australia.
  Support to the research team accommodating AC and HP
• St George's, University of London, UK.
  Kayleigh Kew

External sources

• National Health Medical Research Council, Australia.
  Support for AC and postdoctoral scholarship for HP through a Centre of Research Excellence
• Asthma Australia, Australia.
  Early career fellowship for HP commenced in 2016
• National Institute for Health Research, UK.
  This project was supported by the National Institute for Health Research (NIHR), via Cochrane Infrastructure, Cochrane Programme Grant or Cochrane Incentive funding to the Airways Group. The views and opinions expressed therein are those of the authors and do not necessarily reflect those of the Systematic Reviews Programme, NIHR, National Health Service or the Department of Health.

DIFFERENCES BETWEEN PROTOCOL AND REVIEW

We added an additional secondary outcome: 'Symptoms of asthma' as reported in the Asthma Control Score. This was added after retrieving articles to include that reported Asthma Control Score.
