Abstract

Background: Waitlisted kidney transplant patients suffer from excess cardiovascular events. The benefits of regular cardiac investigations, potentially harmful and expensive, are unknown. We investigate the effectiveness of a cardio-renal MDT in managing high cardiovascular risk waitlisted transplant patients to prevent events and enable transplantation.

Methods: Clinical outcomes in waitlisted transplant candidates managed by our cardio-renal MDT protocol were compared against our standard protocol. Data compared include the transplantation, event, and death rates, cost of cardiac investigations and procedures, and graft, patient survival, and re-hospitalization rates in transplanted patients.

Results: 207 patients were studied (81 standard, 126 cardio-renal MDT). Over 2.7 years, the cardio-renal MDT protocol transplanted more patients than the standard group (35% vs 21%; $P = .02$). The managing cost per patient per year was higher in the standard group (£692 vs £610). This was driven by more echocardiograms and more tests per patient in the standard group ($P < .01$). There was no difference in adverse events or death. There was no difference in re-hospitalization, graft or patient survival rate in transplanted patients.

Conclusions: Our cardio-renal MDT was effective in managing high-risk kidney transplant candidates with greater rates of transplantation and low rates of events at a lower cost.

1 | BACKGROUND

Patients on the kidney transplant wait-list suffer from multiple comorbidities associated with end-stage renal disease (ESRD). This incurs a high cardiovascular event and mortality rate despite already having undergone cardiovascular evaluation to be listed for transplantation.^{1,2} Currently, there is no established protocol on when and how to utilize cardiac investigations in waitlisted transplant candidates. Indeed, cardiac investigations may be used to screen for patients with asymptomatic coronary artery disease (CAD). This may enable the correction of it before being listed again. Occasionally, investigated patients are deemed unsuitable due to unmodifiable cardiac risk and poor prognosis and are subsequently removed from the wait-list. This is to prevent premature cardiovascular mortality at transplantation or soon after. However, screening is potentially harmful and is costly.

The lack of evidenced-based screening methods prompted the start of two randomized controlled trials aiming to determine the optimal strategy to monitor and maintain cardiac fitness in waitlisted patients. The CADScreening trial (NCT02082483) is investigating the benefits of routine screening for CAD in waitlisted patients with myocardial perfusion scintigraphy (MPS) or dobutamine stress echo (DSE) vs selective screening based on symptoms. The CARSK trial (NCT03674307) tests the hypothesis that no further screening after wait-list entry is non-inferior to regular screening for CAD in preventing adverse cardiac events.

As a unit, we have a risk stratification protocol for patients before waitlisting for kidney transplantation. This protocol is relatively successful, evidenced by low peri-transplant death and cardiac event rates.³ Our protocol introduced a cardio-renal multi-disciplinary team (MDT) meeting evaluation for all patients on the transplant wait-list. This study aims to investigate the effectiveness of a structured cardio-renal MDT in managing high cardiovascular risk patients on the kidney transplant wait-list to prevent pre-/peri-transplant cardiovascular events and enabling successful transplantation. This includes rationalizing cardiac investigations in such patients to provide safe kidney transplantation yet minimize invasive investigations.

2 | MATERIALS AND METHODS

This study was an observational audit that compared two cohorts of patients. The control group was managed by our standard protocol, while our cardio-renal MDT managed the interventional cohort. All patients on the kidney transplant wait-list at St. George's University Hospitals NHS Foundation Trust between October 1, 2011, and September 31, 2014, were included in the standard protocol group. Patients were followed from October 1, 2011, to April 30, 2016. All patients on the kidney transplant wait-list at St. George's University Hospitals NHS Foundation Trust between October 1, 2014, and September 30, 2017, were included in the cardio-renal MDT group. Patients were followed from October 1, 2014, to May 11, 2019. This study was approved by the hospital's Clinical Effectiveness and

Audits Committee. As it is an audit, all data are anonymized, and informed consent was not necessary.

Prior to wait-listing, each patient underwent cardiac investigation and risk stratification according to our unit protocol.³ Patients were classified as either high risk (>60 years old or significant CAD [previous myocardial infarction, angiogram with >50% stenosis] or previous cerebrovascular accident [CVA] or significant peripheral vascular disease or had diabetes mellitus) or low risk (those without defined high-risk features).

Waitlisted patients managed with our standard protocol involved being closely followed by their primary nephrologist. The primary nephrologist would determine the initiation of any inter-disciplinary management with cardiology regarding transplant needs. The decision to review patients and examine them in a clinical setting was determined based on clinical need by individual nephrologists and cardiologists. This includes decisions involving the evaluation of patients using cardiac testing.

Waitlisted patients managed with our cardio-renal MDT protocol were closely followed by a primary nephrologist and cardiologist. Patients were also reviewed and examined in a clinical setting based on clinical need throughout the follow-up period. However, patients were additionally routinely discussed in cardio-renal MDT meetings that occurred 4 times a year. Twelve to 14 patients were discussed in a single meeting with each patient discussed for approximately 5 minutes. The meetings were attended by kidney transplant nurses, 1 interventional cardiologist, and 1 non-interventional cardiologist and nephrologists caring for the patients.

High-risk patients were routinely discussed every 2 years since waitlisted, while low-risk patients were routinely discussed every 5 years since waitlisted. Any patient deemed complex by a nephrologist or cardiologist where the decision to maintain wait-list status was not straightforward were discussed in addition to the specified routine intervals. For example, patients with a very complicated history of CAD or were suffering from angina at the time.

The meeting would begin with the nephrologists presenting the patient's relevant clinical findings and the patient's specific concerns if necessary. The cardiologists would then present all the cardiac investigations.

Each patient discussion leads to 3 possible outcomes. First, a patient is deemed too high-risk for surgery and was advised to be removed from the list. The second outcome is to re-evaluate a currently asymptomatic patient on the wait-list, usually with a non-invasive test. The third outcome is the decision to investigate a patient with complex findings or is currently symptomatic. This often prompted advice for coronary angiogram (CA) or invasive cardiac intervention.

The following are the definitions of a positive test: echocardiogram (echo) (wall motion or valvular abnormality), exercise stress echocardiogram (ESE) ($\geq 2 \times 17$ segments abnormal), DSE ($\geq 2 \times 17$ segments abnormal), CA (>50% stenosis in any vessel).

Statistical analyses were conducted using IBM SPSS version 25.0 (SPSS Inc). Kaplan-Meier curves and Cox regression analysis were used to compare the cardiac event rates between different groups, including diabetics vs non-diabetics and those who tested DSE

positive vs DSE negative. Events included acute coronary syndrome, CVA, percutaneous coronary intervention (PCI), coronary artery bypass graft (CABG), or death.

3 | RESULTS

3.1 | Baseline characteristics of patients discussed

A total of 81 patients were included in the standard protocol group. There were 126 kidney transplant candidates included in the cardio-renal MDT group. Twenty-nine patients were discussed more than once, which resulted in 164 cardio-renal MDT meeting patient episodes. Table 1 shows the baseline characteristics of all patients. There was no difference in any clinical or laboratory characteristics between groups. Four patients had previous renal transplants in the standard protocol group. Two patients had previous renal transplants in the cardio-renal MDT group.

3.2 | Procedures performed

Table 2 compares the type and number of cardiac procedures performed between groups. Throughout the study period, 114 and 127 cardiac investigations were done in the standard and cardio-renal MDT groups. Twenty-three percent of patients received no cardiac intervention, 33% had a single intervention, and 43% had multiple interventions in the standard protocol group. Thirty-five percent of patients received no cardiac intervention, 44% had a single intervention, and 21% had multiple interventions in the cardio-renal MDT group. In the standard protocol group, more patients underwent multiple interventions (43% vs 21%; $P < .01$). There was also more

echo performed in the standard protocol group. There was no difference in the number of DSE, ESE, CA, PCI, or CABG performed.

In the cardio-renal MDT group, 96 cardiac procedures were performed as a direct outcome of the MDT discussion. Nine echo, 5 ESE, and 61 DSE were conducted in the repeat evaluation of asymptomatic patients (Figure 1). Thirteen CA, 4 PCIs, and 4 CABGs were conducted in the immediate evaluation of symptomatic patients (Figure 2). Non-invasive testing in asymptomatic patients (echo, ESE, DSE) resulted in a further 19 CA, 10 PCI, and 2 CABG (Figure 1).

3.3 | Patients removed from the transplant wait-list

In the standard protocol group, 12 patients were deemed unsuitable for transplantation and removed from the transplant wait-list. One patient died of a myocardial infarction at the end of follow-up. In the cardio-renal MDT group, 7 patients were deemed unsuitable for transplantation and were removed from the transplant wait-list. Six patients were still alive at the end of follow-up. One patient died of myocardial infarction. Our cardio-renal MDT removed fewer patients based on cardiovascular risk compared to our standard protocol (7 vs 12; $P = .02$).

3.4 | Clinical outcomes—transplantation rate and adverse events

Table 3 compares clinical outcomes between groups. Importantly, more patients were transplanted over the follow-up period if they were managed in the cardio-renal MDT group as opposed to the standard protocol group (35% vs 21%; $P = .02$). There was no difference in mortality or the number of adverse events between groups.

TABLE 1 Baseline clinical and laboratory characteristics

Characteristic	Standard protocol (N = 81)	Cardio-renal MDT protocol (N = 126)	P-value

TABLE 2 Type and number of cardiac procedures performed

In the standard protocol group, there was no difference between transplanted and non-transplanted patients with respect to the following: age ($P = .16$), body mass index (BMI) ($P = .09$), diabetes status ($P = .81$), smoking status ($P = .15$), gender ($P = .33$), hypertension ($P = .23$), hemoglobin ($P = .54$), urea ($P = .92$), parathyroid hormone (PTH) ($P = .23$), phosphate ($P = .21$), ferritin ($P = .80$), length of follow-up ($P = .39$), or positive DSE ($P = .09$). Transplanted patients had higher creatinine ($P = .04$) and cholesterol ($P = .01$) and lower calcium ($P < .01$) at baseline. There was no difference in those who experienced events and those who did not with respect to the following: age ($P = .17$), BMI ($P = .30$), diabetes status ($P = .59$), smoking status ($P = .97$), gender ($P = .23$), hypertension ($P = .90$), hemoglobin ($P = .43$), creatinine ($P = .78$), urea ($P = .90$), PTH ($P = .94$), calcium ($P = .71$), phosphate ($P = .86$), ferritin ($P = .07$), or positive DSE ($P = .88$). Those who suffered events had higher cholesterol ($P = .01$) and shorter follow-up ($P < .01$).

In the cardio-renal MDT group, there was no difference between transplanted and non-transplanted patients with respect to the following: age ($P = .83$), body mass index (BMI) ($P = .29$), diabetes status ($P = .85$), smoking status ($P = .45$), gender ($P = .08$), hypertension ($P = .48$), hemoglobin ($P = .01$), creatinine ($P = .36$), urea ($P = .10$), cholesterol ($P = .98$), parathyroid hormone (PTH) ($P = .52$), calcium ($P = .33$), phosphate ($P = .71$), ferritin ($P = .52$), length of follow-up ($P = .19$), or positive DSE ($P = .43$). There was no difference in those who experienced events and those who did not with respect to the following: age ($P = .65$), BMI ($P = .75$), smoking status ($P = .11$), gender ($P = .20$), hypertension ($P = .75$), creatinine ($P = .81$), urea ($P = .18$), cholesterol ($P = .31$), PTH ($P = .42$), calcium ($P = .45$), phosphate ($P = .80$), ferritin ($P = .10$), or positive DSE ($P = .18$). There were more diabetics with events ($P = .01$), and those with events had lower hemoglobin ($P = .02$) and shorter follow-up ($P < .00$).

Diabetics were more likely to experience events as shown by the Kaplan-Meier analysis in Figure 3 (Log-rank test; $P < .01$) and was the only significant variable on Cox regression when adjusted for age, gender, hypertension, cholesterol, and BMI ($P = .01$). Those with positive DSE results tended to have more events (Figure 4), but this was not statistically significant (Log-rank test; $P = .09$).

3.5 | Clinical outcomes—morbidity and mortality in transplanted patients

Table 4 summarizes the long-term clinical outcomes in transplanted patients between the two groups. There was no difference in hospitalization rates 1 year after transplantation between groups. In the cardio-renal MDT group, 18 patients were hospitalized at least once 1 year after transplantation. There were 23 hospitalizations, of which 4 were due to cardiac causes. Three were due to acute coronary syndrome, and 1 was due to heart failure exacerbation. In the standard protocol group, 7 patients were hospitalized at least once 1 year after transplantation. There were 9 hospitalizations, of which none were due to cardiac causes. There was no difference in the number of total hospitalizations between the two groups ($P = .67$). There was no difference in graft or patient survival at 1 or 2 years after transplantation between groups.

3.6 | Cost analysis

Tables 5 and 6 show the cost of investigations in the standard protocol and cardio-renal MDT protocol groups.⁴ Notably, cardiac stress testing is significantly cheaper than CA, PCI, or CABG. The total cost of cardiac evaluation and intervention for maintaining 81 patients active on the list under the standard protocol was £151 483 or £692/patient/year. The cost of maintaining patients under the cardio-renal MDT protocol was £207 652. The cost at £610/patient/year is more economical compared to patients managed under the standard protocol.

3.7 | Peri-transplant event rates

In the cardio-renal MDT group, 2 patients (6%) suffered from adverse events within thirty days of kidney transplant surgery, as defined previously.^{5,6} One patient had atypical chest pain and a troponin T rise 13 days after surgery, while the other suffered ischemic chest pain 5 days after surgery. Both were treated conservatively. No peri-transplant events occurred in patients managed with the standard protocol.

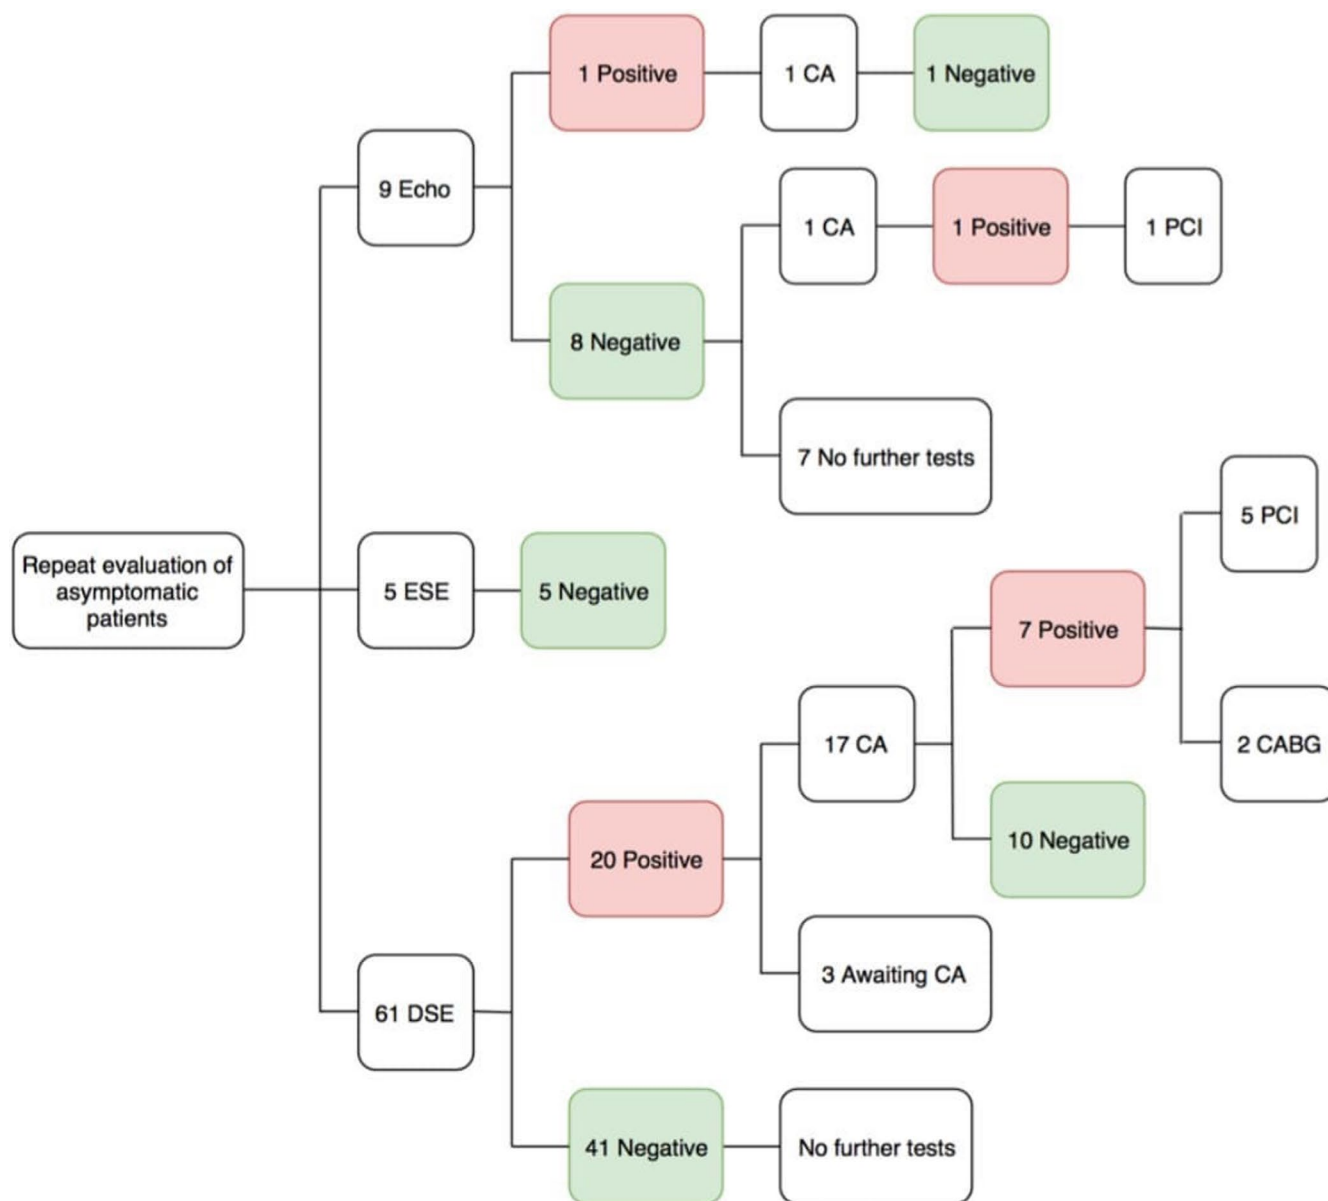

FIGURE 1 Flowchart of investigations conducted in the repeat evaluation of asymptomatic patients. CA, coronary angiogram; CABG, coronary artery bypass graft surgery; DSE, dobutamine stress echocardiogram; Echo, echocardiogram; ESE, exercise stress echocardiogram; PCI, percutaneous coronary intervention

4 | DISCUSSION

This study demonstrates the efficacy of a cardio-renal MDT in managing high cardiovascular risk patients on the kidney transplant wait-list. Over the same duration of 2.7 years, the cardio-renal MDT group transplanted more patients than the standard protocol group (35% vs 21%; $P = .02$) with only 2 peri-operative events. No difference existed between transplanted and non-transplanted patients regarding baseline clinical or laboratory characteristics in the cardio-renal MDT group. In the standard protocol group, those who were transplanted had higher creatinine and cholesterol and lower calcium, demonstrating that those who were transplanted had worse renal function and metabolic risk factors. There was no difference in adverse events or mortality between the two

groups. There was also no difference in morbidity or mortality in transplanted patients, namely patient and graft survival and re-hospitalization rate. Importantly, the cost of cardiovascular investigations and interventions was cheaper in the cardio-renal MDT group at £610/person/year vs £692/person/year in the standard protocol group. The increased cost in the standard protocol group was driven by a higher number of echo conducted and a greater number of patients undergoing multiple cardiac tests. Ultimately, the cardio-renal MDT conducted a more tailored cardiac evaluation, which omitted unnecessary echo. The cardio-renal MDT identified 7 very high-risk patients on the list and removed them. Only 1 of these patients died upon follow-up. In doing so, we were able to prevent the high likelihood of these patients suffering from peri-operative adverse events. Additionally, this allowed donor kidneys

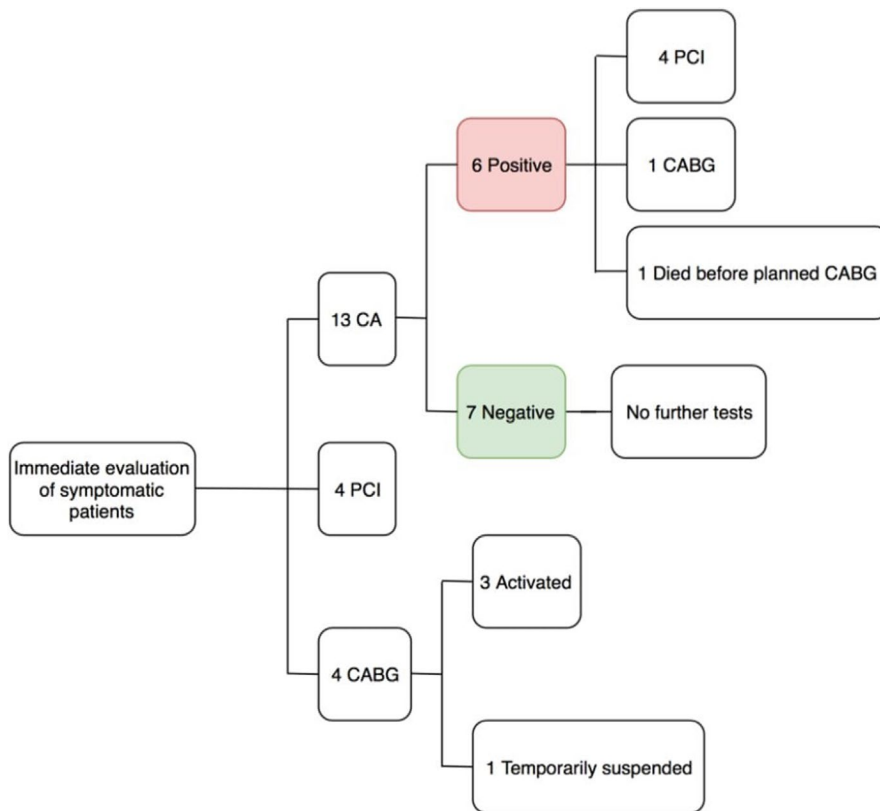

FIGURE 2 Flowchart of investigations conducted in the immediate evaluation of symptomatic patients. CA, coronary angiogram; CABG, coronary artery bypass graft surgery; PCI, percutaneous coronary intervention

TABLE 3 Long-term clinical outcomes

Outcome	Standard protocol (N = 81)	Cardio-renal MDT protocol (N = 126)	P-value
Transplanted	17 (20.99%)	44 (34.92%)	.02
Adverse event	29 (35.80%)	42 (33.33%)	.66
Death	8 (9.88%)	16 (12.69%)	.21

Note: Data presented as number (percentage %).

to be allocated to more suitable candidates who would benefit. Overall, the cardio-renal MDT accepted a higher risk patient population where it refused fewer patients for transplantation compared to our standard protocol. Having a vested cardiology group involved allowed these patients to be transplanted without suffering from worse post-transplant adverse outcomes. Presumably, increased multi-disciplinary team working pre-transplantation allowed for timelier and directed cardiac care post-transplantation. The average cost over 2.7 years to maintain the kidney transplant wait-list with the cardio-renal MDT protocol was £1634 per patient. DSE costs 10x less than CA, with PCI and CABG being even more expensive. Thus, the DSE was useful in ruling out disease to prevent conducting more invasive and costly cardiac investigations and procedures. Diabetics on the kidney transplant wait-list have a 2% higher mortality rate per year compared to their non-diabetic counterparts.⁷ This is consistent with our study, where diabetics suffered more adverse events. We also showed that patients with positive DSE tended to have more events, but this was not statistically significant. This agrees with previous studies done.^{3,8}

The optimal screening method and modality to optimize cardiovascular risk in transplant candidates is not agreed upon. The sensitivity and specificity of DSE in detecting underlying CAD in patients with ESRD has been reported to range from 0.44-0.89 and 0.71-0.94, respectively.⁹ In comparison, the sensitivity and specificity of MPS were 0.29-0.92 and 0.67-0.89, respectively.⁹ Indeed, it has been shown that MPS was only useful for cardiovascular risk stratification in kidney transplant candidates that were determined to be intermediate-risk, not low- or high-risk.¹⁰ In light of this, Mann et al argued that CA is more useful in assessing cardiovascular risk in transplant candidates.¹¹

The contrasting approach by Kumar's group vs Kasiske's group is an example of the lack of clarity to manage these patients best.^{12,13} Kumar et al investigated cardiac survival after pre-emptive coronary angiography in ESRD patients before transplantation.¹² Their pre-transplant practice involves an aggressive approach to invasive cardiac investigations in transplant candidates, where screening CA is conducted liberally, including in all patients >50 years old or with diabetes. In patients who went CA screening and were deemed suitable for wait-list entry, overall survival three years after CA was 97.2% in those eventually transplanted. At the same time, it was 80.7% in those still awaiting transplantation.¹² Ultimately, survival was comparable to our approach, where screening was not restricted to solely invasive and expensive CA. In contrast, Kasiske et al found that a risk-stratified approach to screening waitlisted kidney transplant candidates effectively avoided unnecessary testing.¹³ In their retrospective review of 514 patients, 43.6% were categorized as low risk and did not undergo cardiac screening.¹³

FIGURE 3 Kaplan-Meier curve grouped by diabetes status in the cardio-renal MDT group

FIGURE 4 Kaplan-Meier curve grouped by dobutamine stress echocardiograms (DSE) results in the cardio-renal MDT group

In these patients, the incidence of an ischemic heart disease (IHD) event after waitlisting (before or after transplantation) was 0.5% at 1 year, 3.5% at 3 years, and 5.3% at 5 years.¹³ 56.4% of patients were categorized as high-risk and underwent non-invasive stress

testing or coronary angiography, which resulted in 6.2% and 2.8% of these patients to undergo prophylactic angioplasty or CABG, respectively.¹³ Overall, the incidence of an IHD event after listing in these patients was 3.5% at 1 year, 8.1% at 3 years, and 19.7% at

Outcome	Standard protocol (N = 17)	Cardio-renal MDT protocol (N = 44)	P-value
Hospitalized 1 y after transplantation	7 (41.18%)	18 (40.91%)	.99
Graft survival 1 y after transplantation	17 (100%)	42 (95.45%)	.37
Graft survival 2 y after transplantation	16 (94.11%)	42 (95.45%)	.83
Patient survival 1 y after transplantation	17 (100%)	43 (97.72%)	.53
Patient survival 2 y after transplantation	16 (94.11%)	43 (97.72%)	.48

5 years.¹³ Importantly, of the 68 patients who suffered from an IHD event after being waitlisted, 80.6% underwent screening.¹³ Yet, only 9% of patients screened underwent coronary angioplasty or CABG.¹³ The authors concluded that in light of the relatively low proportion of screened patients who subsequently had an intervention, screening might not be cost-effective in preventing IHD events. Regardless, comparing these two contrasting approaches to our study, our cardio-renal MDT approach was effective and cost-sensitive, considering the transplantation, event, and mortality rate. Teamwork between cardiologists, nephrologists, and kidney transplant nurses improved care by aggregating and combining

a greater amount of knowledge and expertise to make targeted clinical decisions and execute tasks more efficiently. This was evidenced by conducting fewer investigations that lowered cost, and transplanting more patients compared to our standard protocol over the same period. Therefore, it may be more useful to evaluate patients using a multi-modal approach rationalized in a structured MDT discussion instead of restricting assessment using a single pre-specified cardiac investigation or withholding screening altogether. It is important to stress that the annual mortality rate of those who remained on our waiting list is below national averages when managed with the standard or cardio-renal MDT protocol.⁷

Previously, it has been shown that a multi-disciplinary approach can be useful in cardiac risk stratifying kidney transplant candidates.¹⁴ Depending on whether patients were determined to be low, intermediate, or high risk, cardiac testing was performed, which may include an exercise stress test, myocardial perfusion imaging, or CA.¹⁴ Similar to our study, any abnormality on non-invasive testing led to more invasive evaluation and/or intervention. However, there was no mention of the long-term outcomes resulting from this multi-disciplinary approach, including the transplantation, event, and mortality rate. Furthermore, a cost analysis was not done. Therefore, it is difficult to determine the actual efficacy of the study's approach.

Recently, the Cardiovascular Work Group of the Kidney Pancreas Community of Practice of the American Society of Transplantation aimed to summarize key factors that may contribute to sub-optimal cardiovascular care in kidney transplant patients, including during the period of active transplant listing.¹⁵ They stressed that despite the guidance available endorsed by organizations such as the American College of Cardiology, the American Heart Association, the National Kidney Foundation, and the American Society of Transplantation, the management of cardiovascular risk pre- and post-kidney transplantation vary widely amongst different transplant centers.¹⁵⁻¹⁷

Several reasons may explain this. Firstly, there is a paucity of robust data on the optimal screening and management methods for CAD in CKD, as well as the optimal frequency to reassess coronary ischemia in asymptomatic patients.¹⁵ It is unsurprising that this is the case, considering that CKD patients are often excluded from major cardiovascular trials. Screening for cardiac disease in kidney transplant candidates may be important for two reasons. Firstly, to identify patients with asymptomatic CAD to enable either the correction of it or removal of the patient from the list, with the end goal of preventing premature cardiovascular mortality at transplantation or soon after. Secondly, to avoid the misallocation of scarce donor allografts into those who experience early mortality.

Another reason is that the waitlisted patient invariably falls into a "no man's" land, where the responsibility of cardiovascular risk ownership is unclear in the setting of a fragmented model of care consisting of the transplant nephrologist, the evaluating cardiologist, and the referring nephrologist.¹⁵ Thus, the Cardiovascular Work Group urges the development of proactive care models and cardiovascular screening trials to address the waitlisted population of patients.¹⁵ The CADScreening (NCT02082483) and CARSK trial (NCT03674307) will hopefully provide greater insight into the best way to detect cardiovascular disease in such patients. In the meantime, our study shows that a structured cardio-renal MDT meeting is useful in rationalizing cardiac investigations in waitlisted candidates. Furthermore, our protocol replaces the fragmented care actively waitlisted patients experience with a more holistic approach where the whole multi-disciplinary team shares responsibility for cardiovascular risk optimization.

5 | LIMITATIONS

Our study was an observational study without randomization. Hence, it is hypothesis generating and may need data from a prospective randomized study before being universally accepted.

6 | CONCLUSIONS

This is the first study to have evaluated the cost and effectiveness of a standardized cardio-renal MDT meeting in managing cardiac risk amongst kidney transplant candidates. Our cardio-renal MDT managed a group of very high-risk patients at a lower cost but was able to transplant more patients over the same follow-up period compared to our standard protocol. The overall cost was £610/year/patient in the cardio-renal MDT group, and this was achieved using mostly non-invasive cardiac tests and limiting invasive cardiac testing or intervention.
