Abstract
In convulsive status epilepticus (SE), achieving seizure control within the first 1-2 hours after onset is a significant determinant of outcome. Treatment is also more likely to work and be cost effective the earlier it is given. Initial first aid measures should be accompanied by establishing intravenous access if possible and administering thiamine and glucose if required. Calling for help will support efficient management, and also the potential for video-recording the events. This can be done as a best interests investigation to inform later management, provided adequate steps to protect data are taken. There is high quality evidence supporting the use of benzodiazepines for initial treatment. Midazolam (buccal, intranasal or intramuscular) has the most evidence where there is no intravenous access, with the practical advantages of administration outweighing the slightly slower onset of action. Either lorazepam or diazepam are suitable IV agents. Speed of administration and adequate initial dosing are probably more important than choice of drug. Although only phenytoin (and its prodrug fosphenytoin) and phenobarbitone are licensed for established SE, a now considerable body of evidence and international consensus supports the utility of both levetiracetam and valproate as options in established status. Both also have the advantage of being well tolerated as maintenance treatment, and possibly a lower risk of serious adverse events. Two adequately powered randomized open studies in children comparing levetiracetam with phenytoin have recently reported, supporting the use levetiracetam as an alternatives to phenytoin. The results of a large double blind study also including Valproate are also imminent, and together likely to change practice in in benzodiazepine-resistant SE.

Highlights
- Video of seizures in the emergency department can be vital for long term management
- Seizure control within 1-2 hours improves outcome in convulsive status epilepticus
- Non-IV formulations of Midazolam are recommended in the absence of IV access
Valproate or levetiracetam are recommended and may be preferable to phenytoin.

Three large phase IV randomised trials reporting 2019 are changing practice.

**Medical management of Status Epilepticus – emergency room to intensive care**

1. **Introduction**

That status epilepticus (SE) requires emergency treatment has been embedded in practice for decades, and the 2015 ILAE definition [1] emphasises both the need for rapid initiation of treatment and the risk of permanent damage if seizures are not promptly controlled. There are however many types of SE, and it is recognized that outcome is also significantly influenced by seizure type and etiology, as well as the patient’s age and comorbidities. In this review we will focus on the management of early and established convulsive SE for which there is most evidence to guide practice, though management of other types of SE will also be briefly discussed. The management of refractory SE, where seizures have not been controlled by first or second line treatment, is covered in a subsequent article in this supplement.

2. **Does speed really matter?**

It is widely acknowledged that age and etiology are the biggest determinants of outcome in SE. However, historical uncertainty about the influence of duration as an independent predictor has now been addressed by several large case series. It is clear that achieving seizure control within the first 1-2 hours of onset is a significant determinant of outcome [2] as summarized in Table 1. Systemic compromise [3], and brain damage, thought to be caused by a combination of direct damage from seizure-related activity and the secondary effects of the associated metabolic cascade, both contribute to morbidity and mortality. Furthermore, the earlier treatment of SE is instituted, the more likely it is to be successful. In one recent prospective study in children with refractory convulsive SE, benzodiazepine administration beyond the first 10 minutes was independently associated with a higher frequency of death, use of continuous infusions, longer convulsion duration, and hypotension [4]. Unsurprisingly prompt intervention, including pre-hospital, is...
also likely to reduce healthcare costs [5]. Although no individual study can definitively prove cause and effect, a clear message is coming through.

3. General management and diagnostic issues

3.1. First aid and general medical considerations

Key management considerations are summarized in Figure 1. Given the importance of speed it is important to check the time at seizure onset and estimate duration if receiving handover from bystanders or emergency medical services. Guidelines then advocate an ‘ABC’ approach, necessitating that the airway be secured in the first instance. During convulsions, it is muscle (including laryngeal) spasm that restricts air entry, so this is best achieved by stopping the seizures. Any attempt to insert an oral airway may cause injury in an actively seizing patient. Airway manoeuvres such as head tilt and jaw thrust can be helpful post-ictally, though many patients will require a nasopharyngeal airway with oxygen therapy to maintain adequate saturations. Vital signs should be monitored and cardiac monitoring instituted. Cardiac complications are not infrequent [3], and some of the drugs used, particularly phenytoin can also have cardiac side effects. Intravenous access should
be established early, alongside checking blood glucose, with further blood samples sent (see figure 1) to investigate the potential cause and consequences of SE. Investigations are also covered in the preceding article in this supplement. If there are concerns regarding alcohol excess or poor nutrition, 250mg IV thiamine should be given followed by 50mL of 50% glucose IV if the patient is hypoglycaemic.

The above management should all be instituted as rapidly as possible, ideally within the first few minutes of arrival at hospital or pre-hospital where possible. For this reason, amongst others, it is also important to seek help early so that these steps can be carried out in parallel by different members of the multi-disciplinary team.

3.2. Are you sure it’s epileptic status epilepticus?
Whilst not the topic of this article, the importance of considering the possibility that persistent or recurrent convulsions might be dissociative (psychogenic non-epileptic seizures) rather than epileptic status epilepticus must not be overlooked. Frequent admissions should be considered a red flag, and a reported diagnosis of epilepsy is not uncommon – either due to prior misdiagnosis, or a dual diagnosis. There is no fool-proof clinical marker, but key features which can help distinguish dissociative from epileptic seizures are summarized in Table 2. Emergency physicians may be insufficiently experienced to confidently distinguish the two. Perhaps inevitably, the team may initially manage as for epileptic status epilepticus. However, if there is any diagnostic doubt at all, early video recording of the events in parallel with treatment can be extremely helpful to the specialist later called in to advise on longer term management. As with any form of imaging, whilst there is often concern about the sensitive nature of a video, and inability to take consent in this context, video should be considered a critical diagnostic test, and is justifiable as a best interests intervention to inform management [12]. EEG is rarely available in the emergency setting, but expert review of “home” video has been shown to be over 95% sensitive and specific [13] for the diagnosis of dissociative seizures. The use of personal devices for recording is also not precluded, providing appropriate steps to protect the data are applied. These include using a password protected device, disabled cloud syncing, and transferring the files to the hospital records system as soon as possible using encrypted systems. Patient consent can be sought on recovery, and the data deleted if not given, with full documentation of decision making and actions.
throughout this process. Especially considering the risks of inappropriate sedation and intensive care admission in this population, including iatrogenic death [14] and the impact of the correct diagnosis on management, this is surely reasonable.

<sup>a</sup>Can be seen in frontal lobe focal seizures. <sup>b</sup>Patients often report being able to hear what is going on around them but not being able to respond. Features favouring epileptic seizures include prolonged post-event confusion and stertorous breathing. Table reproduced with permission from [17]

4. **Initial pharmacological treatment of convulsive status epilepticus**

First line medical treatments for status epilepticus may be instituted in the community, by emergency medical services or in the hospital. Whilst the focus of this review is on hospital treatment, much of the evidence around initial treatment of convulsive SE comes from pre-hospital studies. The most appropriate drug route will vary depending on the setting and consequent practicalities and safety considerations. There have been dozens of adult and paediatric studies published on the efficacy and safety of benzodiazepines via various routes and several recent systematic reviews/meta-analyses. Methodological heterogeneity, including in study
populations, trial design, primary outcome definitions and approaches to analysis contribute to some differences in conclusions between individual studies. Nevertheless, there is broad consensus to guide first line treatment, as summarized in Figure 2. The majority of trials have focused on the use of benzodiazepines, specifically lorazepam, diazepam, midazolam and clonazepam. The main questions addressed relate to which particular benzodiazepine is preferable in terms of speed of onset and duration of action, safety, and impact of route of administration.

4.1. Intravenous benzodiazepines
For all agents, there is consensus that if intravenous (IV) access is already in place, IV administration of benzodiazepines leads to shorter time to seizure termination [18]. IV lorazepam has been found to be at least as effective as IV diazepam in all meta-analyses performed [19-21] whether in adult or paediatric populations. A potential advantage of lorazepam is its longer duration of action compared with diazepam. Some earlier studies report fewer patients needing repeat doses or additional AEDs to terminate SE, but there is not strong evidence to support superiority of lorazepam. IV midazolam has also been shown to be as effective as both IV lorazepam and IV diazepam, although in practice this has rarely been used as initial treatment [19]. IV clonazepam, which has a long half-life and rapid onset of action, is also widely used across parts of Europe, although the evidence was until recently based only on uncontrolled case series [22]. A randomized prehospital trial in 2016 [23] evaluated the use of IV clonazepam plus either levetiracetam or placebo for the initial treatment of SE. Seizures were stopped within 15 minutes of Clonazepam plus placebo in 84% of patients, so it is clearly effective but has not been compared with other IV benzodiazepines in a clinical trial setting.

4.2. Non-intravenous benzodiazepines
In or out of hospital, unless IV access is already in situ, non-IV routes may be preferable as faster administration can offset the slightly slower onset of action, meaning shorter time to seizure cessation overall. This was demonstrated most clearly in the RAMPART trial, which though set up as a non-inferiority (10% difference) study demonstrated that intramuscular (IM) midazolam is superior to IV lorazepam in the pre-hospital setting [24]. 893 adults were randomized to either drug. 73% of those receiving IM midazolam (10mg in adults, 5mg in children) were
seizure-free when arriving in the emergency department vs 63% receiving IV lorazepam (4mg in adults, 2mg in children), with the main advantage being shorter time to treatment initiation. Intranasal midazolam and buccal midazolam are also effective non-intravenous options for initial management of SE [25], however the existing comparative evidence for these is less strong than for IM midazolam [19]. Arya et al evaluated the efficacy of various non-venous medications for acute convulsive seizures, incorporating data from 16 trials [26]. They concluded that IM and intranasal midazolam exhibit the best efficacy data for treatment of SE in the absence of IV access. Rectal diazepam is also well-established and relatively cheap, effective option. However, non-IV forms of midazolam are not only associated with shorter time to seizure termination but are also more practical and often more socially acceptable to patients and care-givers than rectal medications [25, 27].

There are a number of studies looking at non-IV lorazepam, including intranasal, sublingual or rectal administration [26]. Some studies suggest similar efficacy, but with less consistent data and smaller numbers thus far, such that none are yet recommended as first line options [18].

Overall, the evidence supports use of a non-IV benzodiazepine, preferably Midazolam where IV access is not already present, with choice of agent overall being less important than speed of administration, particularly once IV access is established.

4.3. Non-benzodiazepines as initial therapy for SE
A few studies have looked at alternatives to benzodiazepines as initial treatment in SE. Drugs evaluated include phenobarbital, levetiracetam, sodium valproate and phenytoin. One of the earliest, large randomized control trials in SE [28] demonstrated that IV lorazepam 0.1mg/kg has similar efficacy to both IV phenobarbital 18mg/kg and to combined IV diazepam 0.15mg/kg with phenytoin 18mg/kg. IV lorazepam was significantly more effective than phenytoin alone. Phenobarbital may therefore be an effective option for initial treatment, however in practice this is rarely used due to concerns about long term side effects and potential respiratory depression. Evidence from this trial suggests that phenytoin alone should not be recommended as a first line treatment.
There are no trials comparing sodium valproate alone with a benzodiazepine for initial treatment of SE. Three trials have been undertaken comparing sodium valproate with phenytoin, either alone [29, 30], or in combination with diazepam [31] as first line treatment. All are small and underpowered. One [27] suggested valproate was more efficacious than phenytoin, and one suggested phenytoin had more adverse events [30]. Levetiracetam has also been evaluated as an initial treatment of SE. In an open pilot study IV lorazepam (0.1mg/kg) controlled seizures in 75.6% of patients, compared to 76.3% given IV levetiracetam 20mg/kg as initial treatment of convulsive status [32]. Seizure freedom at 24 hours was also comparable between the two groups. Lorazepam was associated with significantly higher need for intubation and ventilation. Rates of hypotension were also higher with lorazepam administration, though not significantly so. A more recent double-blinded randomized trial analyzed efficacy of levetiracetam with clonazepam vs clonazepam with placebo [23]. In the modified intention to treat analysis, seizures were terminated by 15 minutes in 87% of 68 patients treated with clonazepam and placebo compared with 74% of the 68 pre-hospital patients receiving levetiracetam and clonazepam. There was no significant difference between the two groups.

Thus, as we will go onto discuss, although sodium valproate and levetiracetam may be safe and effective, there is not enough evidence to recommend them as first line treatments of SE, unless and until such time as any clear advantages compared to benzodiazepines are demonstrated which is not yet the case. That both require IV access is also a significant disadvantage as first line treatment.

5. Second line antiepileptics for established SE

Although there is consensus and good evidence to support benzodiazepines as the drug of choice for initial treatment of SE, until recently there was much less evidence to help choose which AED should be used in established SE, when benzodiazepines have failed.

Choice of AED has been largely dictated by availability of IV formulations given the clinical context. Historically only phenytoin or phenobarbitone were used and remain (including fosphenytoin) the only currently licensed medications in established SE.
Phenytoin in combination with a benzodiazepine, and phenobarbitone are both effective as evidenced by the Trieman study cited in 4.3 [28]. However, there is accumulating data suggesting clinical equipoise between phenytoin and newer AEDs such as sodium valproate or levetiracetam. Each has specific potential advantages and disadvantages depending on the clinical context as summarized in figure 3, with a considerable body supporting utility in practice. However, prior to 2019 much of the published data is retrospective, and an published trials had substantial methodological limitations, making it remains difficult to draw firm conclusions. The best comparative data was from meta-analysis [33]. This estimated the efficacy of levetiracetam to be 68.5% (95% CI: 56.2% - 78.7%), phenobarbital 73.6% (95% CI: 58.3%- 84.8%), phenytoin 50.2% (95% CI: 34.2%- 66.1%) and valproate 75.7% (95% CI: 63.7%- 84.8%). However, the quality of evidence is such that this can’t be considered definitive. Most studies had been underpowered; inclusion criteria were variable (many including a mix of convulsive, non-convulsive and focal SE); definitions of treatment efficacy also varied; some included a high proportion with acute symptomatic epilepsy and consequent better outcomes; and most of the existing trials had been open label.

5.1 Phenytoin and fosphenytoin
Phenytoin is one of the oldest drugs used in established SE. As summarized in section 6, current efficacy data suggest a potentially lower efficacy than alternatives. Non-linear kinetics can result in subtherapeutic drug levels, despite recommended dosing at 18-20mg/kg. To what extent this might impact on reported efficacy is uncertain, with levels often not evaluated in trials, but in practice this is still a relevant consideration. Commonly occurring side effects include thrombophlebitis, cardiac arrhythmias (occasionally fatal) and hypotension, particularly in more elderly patients [34]. Of particular note, from reports to the UK National Patient Safety Agency over 5 years [35], phenytoin was the only drug in which loading dose errors were associated with fatalities. Phenytoin also has the disadvantage of exacerbating seizures in some patients with idiopathic generalised epilepsies such as juvenile myoclonic epilepsy.

Its prodrug fosphenytoin has a number of comparative advantages [36], including fewer infusion site reactions, and availability of an intramuscular formulation allowing
for potentially quicker and easier administration. It is considerably more expensive than phenytoin however, and cost-efficacy analyses have yielded contradictory recommendations regarding its use [37, 38]. Furthermore, in contrast to valproate and levetiracetam, phenytoin is not currently recommended as an early maintenance treatment option for epilepsy so loading with another agent may be preferable when continuation treatment is considered. Thus whilst phenytoin has traditionally been the drug of choice in SE and undoubtedly can be effective, there is a growing body of evidence to suggest that other antiepileptics may be preferable on efficacy, safety and practical grounds [35].

5.2 Sodium valproate
Sodium valproate is also a well-established first generation anti-epileptic drug, though it was not available as an IV formulation until 1993. Doses ranging between 25 to 40mg/kg have been shown to be both safe and effective in SE [39]. Overall valproate is well tolerated with a low frequency of adverse events (<10%). In some patients it can cause dizziness, mild hypotension and mild thrombocytopenia. In light of the latter, it may be best avoided in acute stroke. It should also be avoided in patients with known liver disease and/or metabolic encephalopathy. Sodium valproate can be hepatotoxic with the potential to cause an encephalopathy, either with or without raised ammonia. It is also best avoided in patients aged less than 2 years old, particularly if as part of polytherapy, due to increased potential hepatic dysfunction and as yet undiagnosed metabolic problems [40].

Several open label trials have been published comparing sodium valproate with phenytoin for treatment of benzodiazepine-resistant SE [29, 30, 41]. Although meta-analysis demonstrated only a non-significant trend towards valproate being more efficacious [33], but with fewer adverse events, especially less hypotension, compared to phenytoin. For patients who are already taking oral sodium valproate for epilepsy, given that poor adherence is a common provoker of SE, it could be considered the drug of choice. Similarly, it may be preferable in patients with contraindications to phenytoin such as brady-arrhythmias or in those with genetic/idiopathic generalised epilepsy where sodium channel blockers can be aggravating. As such, it is already incorporated in some International SE guidelines [18] as an effective alternative to phenytoin.
5.3 Levetiracetam
Levetiracetam is a 2nd generation well-tolerated anti-epileptic drug which has been available as an IV preparation since 2006. Again, meta-analysis [33] suggests at least similar efficacy to valproate and phenytoin, typically with reported loading doses of at least 20-30mg/kg, totalling between 1-3g. A subsequent small open label study adds to this evidence, with seizure cessation achieved in 78.6% of 30 patients [42]. Adverse events occur in <10%. They tend to be mild and transient, but can include drowsiness, thrombocytopenia, agitation and post-ictal psychosis [43]. Levetiracetam is possibly thus best avoided in patients with known brain injury or mood disorders as it may exacerbate behavioural disturbance. The drug is renally excreted, and so dose adjustments are also recommended in renally impaired patients. Levetiracetam has been shown to be safe when given at much higher doses (40-60mg/kg), with the potential to be more effective than existing studies have demonstrated. Based on current evidence, international guidelines recommend levetiracetam as an option in established SE, with doses of 60mg/kg up to a ceiling of 4500mg [18], despite that, as with valproate, it is not yet licensed for this indication.

5.4 Recent randomised controlled trials
Two phase IV, well powered open randomized controlled trials reported during 2019[44, 45], with results from the pivotal USA double blinded ESETT in adults and children [46, 47] expected imminently. All enrolled individuals with ongoing convulsive SE despite minimum adequate benzodiazepines, and relied on a clinical decision that convulsive SE had ended without other anticonvulsant medication as the primary outcome. Other key methodological differences and the primary outcome results where available are summarised in Table 3. Thus far no significant differences in efficacy have been found. The incidence of key safety endpoints such as life threatening hypotension or arrhythmia was very low, with expected rates of endotracheal intubation, again with no significant differences between the agents. There are methodological pros and cons with each of the studies, too numerous to detail here. However, taking into account the broader safety profiles of each of the agents given in the acute situation together with the practicalities of administration suggests levetiracetam at least may be preferable to phenytoin in most cases,
pending the release from ESETT. Both levetiracetam and valproate can for example be given in less than 5-10 minutes even in a large adult, have fewer drug interactions in a patient group who often have comorbidities or complications needing other treatments, and are commonly used maintenance treatments thereafter.

5.5 Phenobarbitone

Phenobarbitone is also an effective and established drug for treatment of both initial and established SE, with efficacy and safety demonstrated in older [28] and more recent studies [48]. It was first used as an AED in 1912, and has subsequently been developed in formulations for rectal, IV and subcutaneous administration. It is cheap with good global availability, though has fallen out of fashion in developed countries where newer agents are more widely available. Meta-analysis supports comparative efficacy with levetiracetam [33] and sodium valproate [33, 49]. A more recently
published non-blinded Chinese RCT randomised 73 patients to receive either 30mg/kg sodium valproate or 20mg/kg phenobarbital. Valproate had an unusually low efficacy (44.4%), significantly lower than phenobarbital (81.1%) in this study, raising the possibility of ethnic influences on response, though methodological and study population differences may also account for this [48]. The main influence limiting utility of phenobarbitone where alternatives are available however is the higher frequency of adverse events [50] including sedation, hypotension and respiratory depression.

5.6 Lacosamide and other new AEDs
Lacosamide has been available as an IV preparation since 2008. It is licensed as an adjunctive treatment in patients with focal seizures with or without secondary generalisation, and increasingly used in SE, summarized in a recent systematic review [51]. The most common doses used in SE include a loading dose of 400mg with a subsequent maintenance dose of 400mg per day. The most appropriate dose in mg/kg, as would be the more usual approach in SE, has yet to be agreed. Some have suggested 6mg/kg with a ceiling of 600mg, though outside of SE, doses up to 9mg/kg are typically required to achieve therapeutic levels [52]. Side effects include dizziness and rash. Bradycardia and hypotension have also rarely been reported, but overall it is a well-tolerated at these doses, with a low risk of drug interactions.

The majority of studies evaluating lacosamide in SE have been retrospective, descriptive studies with considerable heterogeneity in type of SE (including focal and non-convulsive SE). There was also much variation in the stage that lacosamide was added, even within individual studies. Some were in established status, but most were in either refractory or super-refractory SE. A meta-analysis of these heterogenous studies found lacosamide to be 57% effective overall, and in a post hoc subgroup analysis, it was found to be 92% effective in focal motor SE. Meta-analysis of studies in established convulsive SE [33] found from 13 papers evaluating lacosamide, only 4 patients who were treated with lacosamide second line after benzodiazepine failure, limiting conclusions.

There is clearly considerable interest however, with two more recently published studies: In an open trial from India [53] 66 patients were randomised to valproate or
lacosamide after initial benzodiazepine treatment had failed, with no significant
differences in efficacy though as with all the studies from this group thus far it was
underpowered, and had a high proportion of acute symptomatic seizures. A more
recent randomised non-inferiority prospective study in 2018 compared lacosamide
with fosphenytoin in 74 patients with non-convulsive status [54] and similarly found
no significant differences in efficacy or safety, though there was significant
heterogeneity in the number and choice of other AEDs which had already been
employed.

Overall there is not currently enough evidence to recommend use of lacosamide in
established SE, though arguably also not enough to discount it as an option other
than perhaps in idiopathic generalized epilepsies, where like phenytoin is may be
less effective or even aggravate seizures [55]. A number of case reports and case
series have been published on other new AEDs in SE, including perampanel [56],
brivaracetam [57] and rufinamide [58]. However, unsurprisingly these are typically
used in cases of refractory and super-refractory SE, and it is likely to be many years
if ever before there is sufficient evidence to consider them earlier in the treatment
pathway.

6. Other types of SE
A comprehensive review of treatment for other types of SE is beyond the scope of
this article. Absence status, and myoclonic status in the context of an idiopathic
generalized epilepsy should be treated, though at least for Absence SE there is less
urgency, and ideally with confirmation using EEG. As for convulsive SE,
benzodiazepines are first line, followed by either valproate or levetiracetam. In older
patients, absence status may present de novo, often precipitated by benzodiazepine
withdrawal and will usefully respond to a small dose (e.g.1mg of Lorazepam),
repeated if needed. Initial steps for Focal SE follow the same algorithm as for SE,
but usually with sequential trials of alternative intravenous AEDs sometimes over
days or longer before resorting to sedation. Focal Motor SE (Epilepsia partialis
contrinua) is often drug resistant, and whilst irritating and disabling, rarely
dangerous, meaning the risks of sedation may not be justifiable. For non-convulsive
SE, EEG confirmation will usually be required, but appropriate timing and
aggressiveness of treatment is controversial, and informed by the frailty, cause and
potential outcome for the individual [59]. For patients in NCSE without coma, most would try to avoid ICU if possible. For those with coma, ICU management will often be inevitable, and ongoing management is covered by other articles in this issue.

7. Future potential areas for research
Given the results of the two RCTs already published in 2019, and pending ESETT whether there will be an appetite for further large adequately powered studies in established SE remains to be seen. There is emerging interest in the potential for rapid EEG in the emergency setting, of likely benefit in identifying dissociative nonepileptic seizures (clear alpha rhythm in an unresponsive patient, between convulsive movements excludes epileptic SE as the cause). This could also potentially detect ongoing subtle status in those patients who fail to wake, and prompt administration of additional AEDs, though whether this would influence outcome remains uncertain.

One ongoing concern not yet resolved is how best to support the delivery of evidence-based treatment in routine clinical practice. Despite well established guidelines, numerous studies in multiple settings [60], including within the ESETT study [61] have demonstrated a culture of initial underdosing and delays in the management of convulsive SE, as well as cumulative overdosing with benzodiazepines negatively impacting on patient outcomes. One root cause analysis study exploring this on a paediatric unit [62] identified inconsistency and delays in physician decision making as a key determinant, improved by use of electronic timed “power plans”. Identifying barriers and quality improvement work should be a priority.

8. Conclusions

Speed is of the essence in treatment of SE. Based on current evidence, IV lorazepam or diazepam, or non-IV midazolam remain first choice for initial treatment of SE. Although phenytoin and phenobarbital have been used traditionally, levetiracetam or potentially sodium valproate may be preferable in the majority of patients on current evidence.

Figure Legends
Figure 1. Flow diagram for general and pharmacological management of convulsive status epilepticus
FBC – full blood count; U&E – urea and electrolytes; LFT – liver function tests; CRP – C-reactive protein; Mg – magnesium; TFT – thyroid function tests. PMH – past medical history; AED – anti-epileptic drug; PNES – psychogenic non-epileptic seizure

Figure 2. Benzodiazepines for initial treatment of status epilepticus.
All benzodiazepines can cause respiratory depression, sedation and hypotension at higher doses and in susceptible patients. + relative benefits and – disadvantages

Figure 3. Effective treatment options for established status epilepticus
Min = minute; (fos)Phenytoin doses shown are for phenytoin, or phenytoin equivalents for fosphenytoin. ¹Relative contraindication. Status epilepticus also poses a risk to the woman, and her unborn child. In an emergency situation, especially in a generalized epilepsy or where Levetiracetam is contraindicated, seizure control should take priority. ²Relative contraindication. This patient group anyway at high risk of fatigue and mood disorders, so may be more vulnerable to these adverse effects on levetiracetam.
