Abstract:	<p>Background. Disease models are useful for prospective studies of pathology, for identification of molecular and cellular mechanisms, for pre-clinical testing of interventions and for validation of clinical biomarkers. Here we reviewed animal models relevant to vascular cognitive impairment (VCI). A synopsis of each model was initially presented by expert practitioners. Synopses were refined by the authors, and subsequently by the scientific committee of a recent conference (International Conference on Vascular Dementia 2015). Only peer-reviewed sources were cited.</p> <p>Main Body. We included models that mimic VCI-related brain lesions (white matter hypoperfusion injury, focal ischaemia, cerebral amyloid angiopathy), or reproduce VCI risk factors (old age, hypertension, hyperhomocysteinemia, high salt/high fat diet) or reproduce genetic causes of VCI (CADASIL-causing Notch3 mutations).</p> <p>Conclusions. We concluded that: 1) translational models may reflect a VCI-relevant pathological process, while not fully replicating a human disease spectrum; 2) rodent models of VCI are limited by paucity of white matter; 3) further translational models, and improved cognitive testing instruments, are required.</p>

Response to Reviewers:	<p>Dear Editor RE:BMED-D-16-00665. Translational Models for Vascular Cognitive Impairment. A Review Including Larger Species. Thank you for giving us the opportunity to revise our manuscript. Please find below our point-by-point responses to the comments, marked *****. With best regards, Atticus Hainsworth</p> <p>- Please confirm whether permission to modify the figures 2 and 3 was granted and not just requested. Once permission is granted, please indicate so in the figure legends.</p> <p>***** We have received permission to reproduce modified versions of these figures. This is now stated in the Figure legends for fig 2 and fig 3. (Page 22, 23).</p> <p>- Regarding the addition of Dr Korczyn, I will need an email from each author, confirming they are ok with the addition. Please ask all you co-authors to send the email to both alessandro.recchioni@biomedcentral.com and bmcmecineeditorial@biomedcentral.com as soon as possible. Without the approval of all, we will not be able to proceed.</p> <p>***** An acknowledgement has been added to Professor Korczyn (page 21). The original author list remains unchanged.</p>

3 **58 Abstract**
4

5
6 **59 Background.** Disease models are useful for prospective studies of pathology, for identification of
7
8 **60** molecular and cellular mechanisms, for pre-clinical testing of interventions and for validation of
9
10 **61** clinical biomarkers. Here we reviewed animal models relevant to vascular cognitive impairment
11
12 **62** (VCI). A synopsis of each model was initially presented by expert practitioners. Synopses were
13
14 **63** refined by the authors, and subsequently by the scientific committee of a recent conference
15
16 **64** (International Conference on Vascular Dementia 2015). Only peer-reviewed sources were cited.
17
18 **65 Main Body.** We included models that mimic VCI-related brain lesions (white matter hypoperfusion
19
20 **66** injury, focal ischaemia, cerebral amyloid angiopathy), or reproduce VCI risk factors (old age,
21
22 **67** hypertension, hyperhomocysteinemia, high salt/high fat diet) or reproduce genetic causes of VCI
23
24 **68** (CADASIL-causing Notch3 mutations).
25
26 **69 Conclusions.** We concluded that: 1) translational models may reflect a VCI-relevant pathological
27
28 **70** process, while not fully replicating a human disease spectrum; 2) rodent models of VCI are limited
29
30 **71** by paucity of white matter; 3) further translational models, and improved cognitive testing
31
32 **72** instruments, are required. [162 words]

3 82 ***Introduction***
4
5

6 83

7
8 84 Vascular cognitive impairment (VCI) is a spectrum of clinical disease states [1-4]. These range from
9
10 85 post-stroke mild cognitive impairment or dementia following a large artery stroke, through
11
12 86 “sporadic” small vessel disease, to pure genetic small vessel arteriopathy (CADASIL, CARASIL,
13
14 87 *COL4A1/4A2* mutations) [1, 5, 6]. The most common pathology underlying VCI is cerebral small
15
16 88 vessel disease (SVD) which leads to focal lacunar ischaemic infarcts, diffuse white matter lesions,
17
18 89 and small haemorrhages in deep brain areas [3, 4]. These disease states manifest in a spectrum of
19
20 90 cognitive impairments. Further complexity arises, as most clinical dementia in older persons is
21
22 91 likely to be “mixed” as a result of AD combined with vascular pathology [7, 8]. While
23
24 92 characterization of the neuropathological and radiological features of human VCI has improved over
25
26 93 the last two decades (see adjoining articles) the molecular changes that underpin these
27
28 94 characteristics remain elusive [6]. In VCI we currently lack symptomatic treatment (comparable to
29
30 95 donepezil for AD) and molecular targets (comparable to tau, APP and A β).
31
32
33
34
35
36
37
38
39

40 96

41 97 Because VCI arises from a spectrum of diseases, no single model will reproduce all pathological and
42
43 98 cognitive features of SVD or VCI [6, 9-12]; see Table 1. Furthermore, as with any animal model for
44
45 99 dementia, the behavioural-cognitive phenotype of any given model can never fully represent human
46
47 100 cognitive deficits. We define a “translational” model as one that impacts on clinical practice [13].
48
49

50 101 Therefore, in order to be translational any animal model should reproduce at least one of the

51 102 pathological processes in human VCI [6, 12, 14]. A fully translational model would permit: i)

52 103 prospective studies of the timescale and the sequence of events, during development of the

53 104 pathological process, ii) identification of novel molecular, cellular and physiological mechanisms,

54 105 iii) pre-clinical testing of drugs and other interventions, for proof-of-concept studies, iv) pre-clinical

106 testing of safety profile of drugs, optimal dosing and time-scale, v) validation of clinical biomarkers
107 and endpoints, such as radiological or biochemical signatures. Models representing the initiating
108 factors would allow translation of preventive strategies, whereas models of advanced disease states
109 allow testing of therapeutic interventions. It is appropriate and timely to seek international accord on
110 such models [15]. Following a recent NIH-sponsored Alzheimer's Disease-Related Dementias 2016
111 Summit (<https://meetings.ninds.nih.gov/Home/Tab1/11958>) recommendation #1 for VCI was to
112 “Establish new animal models that: (i) reproduce small vessel disease and other key pathogenic
113 processes thought to result in cognitive impairment; (ii) are easily applicable to both VCID and AD
114 research for advances in mixed etiology dementias; (iii) address vascular contributions to dementia
115 via both white matter and grey matter or (iv) include genetic and acquired conditions that are
116 associated with VCID”.

117
118 Here we review published models relevant to VCI, including rodents and emphasizing larger
119 species. This review is the result of discussions between experts from 12 laboratories across seven
120 countries. Relevant systematic reviews are available [10, 12].

121
122 **** Table 1 near here

123
124 *Overview of Experimental Species*

125 **Rodents.** We have included models of focal ischaemia (middle cerebral artery occlusion, MCAo)
126 [16-19] as this is a validated, translational model of cerebrovascular injury. Global hypoperfusion
127 models include bilateral carotid artery occlusion (BCAo) in rats [20], and bilateral carotid artery
128 stenosis (BCAS) using wire coils in mice [21, 22]. A refinement of the BCAo protocol employs
129 constrictor cuffs to give a gradual arterial occlusion over ~1-2 days [20]. These global models

65

130 produce ischaemic white matter lesions, likely reflecting the low baseline perfusion of white matter.
131 Other pathologies can also occur, including hippocampal cell death, small haemorrhages and
132 vascular amyloid deposition. Genetic alterations include inbred strains (e.g. SHR, SHRSP) [23-26]
133 or transgenic manipulations (e.g. *Notch3* mutant strains) [27-29]. VCI-relevant animals can also
134 result from manipulation of risk factors, such as age, hypertension, diabetes mellitus,
135 hyperhomocysteinemia or high salt-high-fat (“fast food”) diet [14, 25, 26, 30, 31].

136

137 **Larger Species.** Larger animals have longer natural life span than rodents. Experimental ruminants
138 (sheep, goats) are predominantly used to simulate acute cerebrovascular pathologies such as
139 ischaemic stroke [32-34] and cerebral haemorrhage [35]. In domestic dogs, hypercaloric or
140 unbalanced diet, lack of physical exercise and dyslipidemia are prevalent [36]. As in humans,
141 hypertension is often observed in older subjects [37] as is cerebral arteriosclerosis [38].
142 Consequently, a canine cognitive dysfunction syndrome (CCDS), featuring some clinical aspects of
143 VCI, has been described, particularly in breeds living long enough (>9 years) to fully develop a
144 neurological phenotype [39-42]. In cats, less is known about the relation between aging, vascular
145 pathologies and cognitive decline. A β and tau pathologies have been described in cats showing
146 clinical signs of cognitive decline [43-45]. Hypertension associated with arteriosclerosis, as well as
147 small, multifocal cerebral haemorrhages, were also reported for felines [46].

148

149 Behavioural paradigms for cognitive assessment in larger species have been reported from specialist
150 centres for sheep, pigs and cattle [41, 47-51]. The most advanced cognitive abilities are seen in
151 primates, for which sophisticated cognitive tools have been developed [52, 53]. Dietary
152 manipulation and hypercaloric diet can decelerate microvascular pathologies and cognitive decline

65

153 in primates [54, 55], without changing lifespan [56]. Nevertheless, physiological aging can take
154 decades in primates, and studies relevant to VCI may be restricted to specialized colonies [57, 58].
155
156 Large animal models allow clinical neuroimaging without significant limitations in resolution,
157 acquisition time or data analysis. MRI protocols are now available for dogs [59], cats [60], non-
158 human primates [61-63], pigs [64, 65] and sheep [66]. MRI (T1, T2, FLAIR) is advantageous for
159 analysis of tissue volume and lesions [66], as well as for anatomical evaluation of particular brain
160 areas [67]. Perfusion and diffusion-weighted sequences reveal cerebral blood flow (CBF) dynamics
161 and vascular permeability [68]. Templates, automatic segmentation and labelling routines for larger
162 species are essential for studies aiming at quantitative morphometric analysis of MRI and/or PET
163 images. Automatic labelling and processing routines have been developed for rhesus and
164 cynomolgus monkeys [61, 69, 70], sheep [67], pigs [71, 72], and dogs [73]. This enables efficient,
165 observer-independent analysis of grey and white matter regions.

167 **Method of this review**

168 For each model, expert practitioners used web-based searches and their own expertise to write a
169 section of the review. All synopses were circulated for editing by all authors, and subsequently by
170 the scientific committee of an international conference (International Conference on Vascular
171 Dementia, ICVD2015, Ljubjiana, Slovenia). Only peer-reviewed sources in English were included.

172
173 *Ethical statements on animal data presented here.* Sheep experiments from which data were derived
174 (Figure 1) were approved by the responsible authorities for University of Lübeck and University of
175 Leipzig, Germany (animal protocol numbers TVV33/09, TVV09/11, TVV33/12). Experiments
176 using monkeys (Figure 2) were approved by the Institutional Animal Care and Use Committee of

177 Boston University Medical Center. All procedures with dogs in Figure 3 were conducted in
178 accordance with University of Kentucky approved animal protocols (2009-0483) and the NIH
179 Policy on Humane Care and Use of Laboratory Animals.

180

181 **Expert Reviews of Specific Models**

182

183

184 ***Large Vessel Ischaemia. Middle Cerebral Artery Occlusion (MCAo) in Rodents***

185 MCAo induces acute focal ischaemia bordered by a partially ischaemic penumbra [74, 75]. While
186 recovery of sensorimotor function is well-characterised using behavioural tests, there is less
187 literature on cognitive impairment [76]. Spatial learning, assessed by Y- and T-maze tests, is
188 hippocampus-dependent but as other regions are also required, including prefrontal cortex and basal
189 forebrain, these tests are relevant to the MCAo model [77]. Following MCAo, male rats showed
190 decreased rates of spontaneous alternation compared with sham-operated animals at day 21 post-
191 stroke [78]. At 4 days post-MCAo, male mice spend less time exploring a novel object than sham
192 animals [79]. Fear-motivated tasks such as passive avoidance have also been used to assess
193 cognitive impairment after stroke [80]. While passive avoidance is a simple task, it is stressful so
194 could confound results of other behavioural tests [76].

195

196 ***Larger Species: Sheep with Vascular Ischaemic Lesions***

197 Permanent [32] and transient [34] MCAo have been performed in sheep, resulting in well controlled
198 and reproducible lesion sizes (Figure 1). Histopathological investigations revealed both grey and
199 white matter changes, including glial scar formation, microglial activation and replacement of the
200 tissue by new formation of blood vessels and foamy fat cells [33]. Moreover, ovine models have
201 been successfully employed to test experimental therapeutic paradigms in short term [81] and

202 longer-term (up to 7 weeks) approaches [33], during which benefits of single- and multi-mode
203 imaging protocols became evident.
204 Figure 1 near here*****
205 A caveat in this species (and other domestic mammals) is the *rete mirabile epidurale rostrale*, a
206 local arborisation within the carotid artery [82]. This often necessitates a transcranial approach for
207 MCAo. Leaving the trepanation covered only by soft tissue reduces intracranial pressure, which
208 greatly increases long-term survival. In mild and severe global cerebral ischaemia models in sheep,
209 it became evident that the basilar artery can contribute a higher proportion of CBF than in humans
210 [83]. After prior bilateral clamping of both common carotid arteries for 4-30 min, no lesions were
211 found in brains of sheep subjected to the method for <10 min. Longer duration produced neuronal
212 changes of several brain regions, similar to those described in other species.

213

214 ***Primates and Rodents: Chronic Brain Hypoperfusion***

215 With the assumption that reducing CBF is a common feature of VCI [3, 84, 85], the original mouse
216 BCAS model was developed by placing microcoils on the carotid arteries to induce cerebral
217 hypoperfusion [86]. While complete ligation of the carotid arteries (i.e. BCAo) substantially
218 increased mortality, mice can withstand up to 50% BCAS [22, 87]. Monitoring cognitive function
219 using Y maze, radial arm maze, Barnes maze and Morris water maze has provided robust evidence
220 that the BCAS model replicates some features of VCI, in particular the deficit of working memory.
221 In BCAS global CBF drops rather abruptly. With the same principle as BCAS, ameroid micro-
222 constrictors made of casein (which swells on absorbing water) were placed around the carotid
223 arteries to provide a more gradual stenosis [20]. Ameroid constrictors have also been applied to
224 spontaneously hypertensive rats [20]. Further refinements have allowed the development of mice
225 models which exhibit subcortical infarcts and white matter damage by surgical implantation of an

226 ameroid constrictor to the right common carotid artery (CCA) and placement of a microcoil to the
227 left CCA to induce approximately 50% arterial stenosis. This is referred to as gradual carotid artery
228 stenosis (GCAS) [88]. There was gradual reduction of CBF over 28 days, and multiple infarct
229 damage in right subcortical regions, including the corpus callosum, internal capsule, hippocampal
230 fimbria, and caudoputamen in 81% of the mice [88, 89]. These hypoperfusion models are discussed
231 further elsewhere [12].

232 A baboon (*Papio anubis*) model evaluates if partial cerebral ischaemia or oligaemia resulting from
233 reduced blood flow to the brain induces white matter pathology consistent with SVD or AD-like
234 changes. The baboon is ideal to relate to AD because it exhibits both amyloid beta and tau
235 pathology with ageing and carries *APOE4* associated with AD pathology. Adult, male baboons
236 were subjected to three vessel occlusion (3VO) by complete ligation of the internal carotid arteries
237 bilaterally, and occlusion of the left vertebral artery. We have recently reported subcortical and
238 white matter changes in animals to 28 days after 3VO [90]. This model is useful to evaluate
239 interventions at various stages and specifically examine the effects of ageing, high fat diet,
240 hypertension and neuroinflammation. Ameroid constrictors to replicate a gradual reduction in CBF
241 may be a future refinement [84, 85].

242

243 ***SHRSP with modified diet or hypoperfusion***

244 Hypertensive rat strains can undergo white matter changes [23-26, 91]. SHRSP typically live for 9-
245 12 months before developing ischaemic and haemorrhagic stroke lesions [12, 92]. When a low-
246 protein, high salt diet is given to the SHRSP, lesions and death are accelerated [93]. Starting the diet
247 after 6 weeks of life leads to haemorrhagic strokes, but delaying the onset of the diet until the 12th
248 month slows the onset of strokes and allows the damage to the white matter to occur earlier [25].
249 The white matter damage results from hypoxic hypoperfusion [94]. In a recent study minocycline, a

250 tetracycline derivative with the ability to inhibit matrix metalloproteinases, reduced white matter
251 damage and reversed the behavioural changes in SHRSP [26]. For more extensive discussion of
252 SHRSP, see [12, 92].

253

254 ***Dietary Induction of Hyperhomocysteinemia***

255 Elevated circulating homocysteine (hyperhomocysteinemia) is caused by a variety of genetic,
256 physiologic and dietary conditions, which have been extensively studied in rodents [95-98]. These
257 cause cognitive impairment in *ApoE* null mice, transgenic mouse models of Alzheimer's disease,
258 and wildtype mice and rats [31, 99, 100] with surprisingly little neurodegeneration or inflammation.
259 Feeding wild type C57BL6J mice a diet deficient in three B-vitamins (folate, B12 and B6) for 10
260 weeks resulted in hyperhomocysteinemia, microvascular rarefaction and impaired performance in
261 the Morris water maze [31, 100]. The same dietary regime in APP transgenic mice worsened
262 cognitive impairment [101], and in combination with excess methionine in dual mutant APP/PS1
263 mice, the diet induced the redistribution of amyloid from brain parenchyma to the microvasculature
264 along with micro-haemorrhages, as determined by histology and MRI [30, 102]. In Sprague Dawley
265 rats, folate-deficiency alone was sufficient to induce homocysteinemia and cognitive impairment,
266 and to reduce cerebral blood volume and reactivity measured by absolute, non-invasive near infra-
267 red spectroscopy [103-105]. For further discussion of hyperhomocysteinemia models, see [12].

268

269 Dietary modification can be applied to most species, models and co-morbidities. Caveats are that
270 dietary models typically have higher variability and more subtle effects than genetic or
271 pharmacological models. Outcomes are sensitive to dietary formulation and feeding. This
272 underscores the need for biochemical and metabolic verification of the diet in brain and periphery.
273 While chronic folate and B12 deficiency in humans causes macrocytic anaemia and

274 myeloneuropathy, these outcomes are almost never observed in rodent models. Associations
275 between microvascular rarefaction and cognitive impairment, in the absence of neurodegenerative
276 changes, have been observed in other models, including mice fed high fat diet [106], aged rats [107],
277 and irradiated rats [108].

278

279 ***Primates with Chronic Hypertension***

280 The basis of this model is the induction of hypertension, by surgical coarctation of thoracic aorta in
281 the rhesus monkey [52, 109-111]. A segment of the thoracic aorta is mobilized and dissected
282 without injuring the mediastinal and intercostal branches. The external diameter of the same
283 segment is measured and then narrowed to luminal diameter of 2.0-2.5 mm (Figure 2). A pressure
284 transducer inserted into the femoral artery is advanced through the surgical site. Typically,
285 systolic/diastolic pressure is 170/100mmHg above the coarctation, and 80/50mmHg (normal for
286 rhesus monkeys) below.

287 Given the known effects of chronic hypertension on attention, memory, and executive function in
288 humans, these domains were assessed in adult primates (5-11 years of age). The tasks were: (1)
289 automated task of simple attention: (2) two tasks of memory function, the delayed non-matching to
290 sample task (DNMS) [112, 113] and the delayed recognition span task (DRST) [114, 115] and (3), a
291 primate analogue to the Wisconsin Card Sort task, the Conceptual Set-Shifting Task (CSST) [116].
292 Performance was compared with sham-operated controls that underwent every stage of the surgical
293 procedures up to, but not including narrowing of the aorta. Animals with coarctation were grouped
294 into Borderline (135-150 mmHg) or Hypertensive (>150mmHg).

64
65

296 On the task of simple attention in which monkeys are required to select the same target stimulus on
297 the touch-screen, there was a positive correlation between response time and systolic and mean
298 blood pressure. Hypertensive (but not Borderline) animals were significantly impaired relative to
299 the sham-operated group.

300 Hypertensive monkeys were impaired on a task that required orienting to, and then responding by
301 touching, a randomly-presented visual stimulus. Unlike normotensive animals, Hypertensive
302 monkeys did not benefit from the presentation of a cue that preceded the target stimulus. The effect
303 did not appear to be related to motivational state as there was no difference in the number of missed
304 trials. These findings suggest a reduction in the speed of processing in the stimulus-response chain.

305 The findings on memory assessment revealed a significant difference among the groups on the
306 DNMS up to 12 months post-surgery. Hypertensive monkeys re-learned the DNMS task less
307 efficiently than sham-operated controls (Figure 2). On both the spatial and pattern conditions of the
308 DRST, the performance of the Hypertensive monkeys was significantly impaired with respect to the
309 control monkeys suggesting that, in addition to affecting attentional function, hypertension produced
310 an impairment in “rule learning”.

311 ***** Figure 2 near here

312 The CSST requires the monkey to establish a cognitive set based on a reward contingency, to
313 maintain that set for a period of time, and then shift the set as the reward contingency changes. A
314 subset of Hypertensive monkeys were unimpaired on the initial phase of the CSST (a simple three
315 choice discrimination). In contrast, Hypertensive monkeys were impaired at abstracting the initial
316 concept of colour on the CSST and subsequently were impaired when shifted to the concept of
317 shape, when shifted back to the concept of colour, and again when shifted back to the concept of
318 shape. The findings from this task suggest that the two groups of monkeys were able to learn a

1
2
3 319 stimulus reinforcement contingency at the same rate and that the impairment seen on the CSST is
4
5
6 320 most likely one of abstraction and cognitive flexibility.
7
8
9 321 Overall, hypertension significantly influenced higher cognitive function. Blood pressure correlated
10
11 322 with a composite z-score (similar to an I.Q. score), suggesting a direct relationship between BP and
12
13 323 cognition (Figure 2).
14
15
16 324 Various neuropathologies are seen in this primate model, including tortuous small vessels,
17
18
19 325 hemosiderin-filled macrophages and, most conspicuously, micro-infarcts in both grey and white
20
21 326 matter [110, 111]. The micro-infarcts are of irregular shape and relatively-uniform size (average
22
23 327 maximum diameter ~ 0.5 mm). In the grey matter these lesions were characterized by a total loss of
24
25
26 328 neurons, and in white matter by marked loss of myelinated fibres.
27
28
29
30
31

32 330 ***Larger Species: Aged Canine Model***

33
34
35 331 Aging dogs spontaneously develop cerebrovascular pathology linked to cognitive decline [41, 42]
36
37 332 including cortical atrophy and ventricular enlargement (Figure 3). Cognitive impairment was
38
39
40 333 evident on measures reflecting learning and memory, and a subset of aged animals became severely
41
42 334 impaired [41, 42]. A strength of the model is that beta-amyloid (A β), critically involved with plaque
43
44 335 accumulation and CAA, is very similar in dogs and humans [117-119]. Vascular and perivascular
45
46 336 abnormalities and cerebrovascular A β pathology are frequently found in aged dogs [40, 120-124].
47
48
49 337 Dogs may be a suitable model system in which to examine the consequences of CAA on cognition
50
51 338 [125]. As in humans, canine CAA is associated with cerebral haemorrhage [40, 121], the occipital
52
53
54 339 cortex being particularly vulnerable [126]. Several environmental manipulations and
55
56
57 340 pharmacological studies that modify lifestyle factors have been successfully implemented in canine
58
59 341 models, with some showing significant benefits to cognition [41]. Canines have also been used as a

342 model for ischaemic stroke. Both FLAIR and T2* (sensitive to hemosiderin) imaging show
343 significant white matter hyperintensities (WMH) [127]. Loss of white matter integrity may be a
344 consequence of CAA. For example, dogs ranging from 1-20 years, exhibited a progressive loss of
345 myelin basic protein, correlated with age and with increasing CAA [128].

346 *Figure 3 near here ******

347 The canine brain displays substantial age-associated morphological change [129-131]. Gadolinium-
348 enhanced MRI revealed reduced BBB function with age, as well as reduced cerebrovascular volume
349 [129]. Characterizing cognitive function in aging dogs requires many months, and treatment studies
350 may take several years. In comparison to rodent models, they require significant veterinary care as
351 they become older. Radiological outcome measures that reflect in vivo CAA (e.g. SWI scans) have
352 not yet been published.

353

354 ***Mouse Models for Monogenic Small Vessel Disease (CADASIL)***

355 CADASIL (Cerebral Autosomal Dominant Arteriopathy with Subcortical Infarcts and
356 Leukoencephalopathy) is a monogenic archetype for SVD, caused by cysteine-altering missense
357 mutations in *NOTCH3*. CADASIL patients develop progressive white matter lesions from early
358 adulthood, followed by cognitive decline and recurrent subcortical infarctions [132]. Conventional
359 transgenic murine models, expressing mutant human *NOTCH3* from a cDNA construct [133-135]
360 recapitulate some aspects of CADASIL vascular phenotype (vascular Notch3 accumulation, and
361 granular osmiophilic material on electron microscopy), see [12, 92]. In only one transgenic model,
362 with 4-fold overexpression of mutant Notch3, the mice developed disturbed cerebrovascular
363 reactivity (from 5 months of age), reduced CBF (12 months) and white matter damage (18 months)
364 [27]. A novel transgenic mouse strain has recently been developed [136], containing genomic

365 human *NOTCH3*. These animals show early-onset vascular Notch3 accumulation (from 6 weeks)
366 [136]. A knock-in model, made by introducing a mutation in endogenous *Notch3*, developed a
367 CADASIL clinical phenotype (20 months of age) [137]. Stroke lesions, microbleeds and motor
368 deficits were seen only in a minority of mutant mice (5-12%). Despite the fact that cognition has not
369 yet been characterized in these murine models, they offer a valid patho-genetic representation of
370 human CADASIL, and may be an important pre-clinical model in which to test VCI therapies for
371 efficacy.

372
373

Discussion and Conclusions

374
375
376 As noted previously [9-11, 14] no experimental model replicates all pathologic and cognitive
377 aspects of human VCI (see Table 1). Animal models are useful to reflect a pathological process
378 (e.g. white matter hypoxia, arterial fibrosis, amyloid accumulation) rather than a human disease. Old
379 dogs with CCDS, and aged primates (>20 years of age) being possible exceptions, none of the
380 models discussed here results in a "demented" animal. That said, all the animal models considered
381 above reproduce at least one of the pathological processes in human VCI. Because the sequence of
382 events leading from experimental challenge to brain pathology, and so to VCI, can be characterized
383 in animal models (and interventions imposed), the models may help to identify pathways that lead to
384 VCI. As the pathogenesis of SVD, the commonest cause of VCI, remains unknown, a valid model
385 of SVD-dependent VCI remains a challenge. Making these conceptual and biological limitations
386 explicit will expedite the development and appropriate use of translational models for VCI.

387

388 There are several general limitations in the extant literature. Most animal studies involve short-term
389 follow-up (typically, less than 4 weeks). Male animals are generally used, females usually avoided
390 due to influences of the reproductive cycle. Few studies have correlated cognitive changes with

391 anatomical changes, as seen by pathology or MRI. Most of the available cognitive paradigms are
392 derived from AD models. Many experimental studies are under-powered (i.e. use a small number of
393 animals) and few are replicated.

394

395 We have a number of recommendations for the VCI research community. First, it would be
396 advantageous to increase our knowledge and experience in larger species with more abundant white
397 matter and gyrencephalic brain anatomy. This is especially important given the central role of white
398 matter lesions in human VCI. Second, robust neuropsychological methods for assessing VCI in
399 experimental animals (particularly larger species) would be beneficial. Cognitive impairment (and
400 recovery) are the most complex aspects of human VCI, and will likely differ between animals and
401 humans (for example, experimental species lack spoken language). Thus, aspiring to a precise
402 behavioural replication in an animal may not be possible. Nevertheless, a core toolkit of validated,
403 reproducible, species-appropriate tests of cognitive phenotype is required. With respect to SVD,
404 simple behavioural indicators analogous to the key cognitive features of the syndrome in humans
405 (impaired processing speed, apathy and executive dysfunction) should be welcome.

406

407 Third, progress on translational VCI models will be more rapid if high standards of “Methodological
408 quality” [15] outlined in ARRIVE guidelines[138] and in previous translational consensus
409 documents [139, 140] are followed. Specifically, random allocation of animals to experimental
410 groups and blinded assessment of outcomes was quite rare in earlier studies (pre-2010) [10]. Future
411 experimental studies should adhere to available guidelines on experimental design, regarding *a*
412 *priori* statistical power calculation, randomization, blinding of observers, and confirmation by at
413 least two independent laboratories [15, 138-140]. It appears likely that negative outcomes of animal
414 studies are rarely published.

438

Fourth, as neuroimaging (particularly MRI) has a central role in human VCI, future pre-clinical studies will be enhanced by brain imaging data. Radiological features (diffuse white matter lesions, lacunar infarcts) are the main clinical biomarkers of SVD. Hence correlative studies relating MRI to brain pathology in animals will continue to be informative.

Experiments using gyrencephalic species may be costly and long in duration, to afford sufficient statistical power. A possible solution is a step-wise approach that employs rodents to study fundamental aspects of cerebrovascular disease common to all species, and large animals to study aspects of VCI that require a large gyrencephalic brain. Extending studies across species will clarify molecular, cellular and physiological events that lead from vascular disease to neuronal injury and cognitive dysfunction in humans, and improve the likelihood of achieving new preventive and therapeutic interventions in VCI.

Declarations

Ethics approval and consent to participate
Human data or human tissue: Not applicable. Animal experiments: see Methods section.

483 **Figure 1. Focal ischaemic lesions in ovine brain.**

484 A, adult sheep brain in coronal section. T1-weighted population-averaged brain template (left),
485 depiction of grey and white matter, as well as cerebrospinal fluid (middle panel, overlay on
486 template) and surface reconstruction of white (white) and grey matter (yellow) in stereotactic space
487 (right). Grey and white matter spaces are derived from *a priori* tissue probability maps.

1
2
3 488 B, focal ischaemic lesion, 6h after permanent middle cerebral artery occlusion (MCAO).
4
5
6 489 Hyperintense area is seen in the left temporal cortex and medulla, in T2-weighted TSE MRI (left-
7
8 490 top). In this area, a decreased diffusion in apparent diffusion coefficient maps of diffusion weighted
9
10 491 imaging (DWI-ADC, left-bottom) is visible. Fractional anisotropy map of diffusion tensor imaging
11
12 492 (DTI-FA, middle panel) reveals a loss of fibre integrity. Following sacrifice and brain removal, the
13
14 493 mitochondrial marker TTC labels living cells (red). The ischaemic lesion is unlabelled by TTC
15
16 494 (right).

Table 1. Features of VCI, as related to experimental models considered.

	MCAo Rats, mice	MCAo Sheep	Chronic hypo- perfusion Rats, mice	Chronic hypo- perfusion Baboons	HHCy Rats, mice	Chronic HT: SHRSP	Chronic HT: monkeys	Aged dogs	CADASIL mice
Cognitive changes: executive function, attention, processing speed, apathy/reward seeking, memory decline	deficits in spatial and recognition memory; passive avoidance.	post-stroke apathy; higher cognitive function NR	Working memory and reference memory deficits	NR	Impaired spatial learning, working memory	Spatial memory impaired	Reduced executive function, attention, short-term memory	Executive function, spatial learning and memory; visuo- spatial function, simple associative learning; open field activity, anxiety, dis- orientation; restlessness	NR
Sub-cortical motor symptoms: Impaired gait, balance, posture	Sensori- motor deficits. Severity depends on lesion size.	Sensori- motor deficits reflecting lesion size and location	motor deficits on rotarod (GCAS mice). No motor deficits reported for	NR	NA	Sensori- motor deficits. Severity depends on lesion type, location, size	NA	NR	Motor deficits in some aged animals

			BCAS						
Risk factors: age, hypertension, DM, obesity	some studies: age, HT, obesity	NR	HT (SHRSP)	NA	HHCy Co-morbidities e.g. mutant APP	HT, dietary risk factors (high fat, high salt); hypo-perfusion	HT	Age (obesity?)	Notch3 mutation
Brain gross pathology: atrophy, large infarcts..	Focal ischaemic lesion; cortical and striatal	Focal ischaemic lesion; atrophy and pseudo-cyst in chronic stage	NA	NA	NA	Ischaemic lesions and He; variable extent, location	NA	Ventricles enlarged; brain atrophy; spontaneous lesions	NR
Brain neuropathology: Lacunes/micro-Hge, micro-bleeds, diffuse WML	Rapid cell death in ischaemic core. Leukocyte infiltration, neuro-inflammatory changes. Delayed damage in remote areas.	acute cell death in core; inflammatory response; leptomeningeal and vascular re-organisation; delayed neuroinflammatory response in remote areas	Diffuse WML; micro-Hge; Impaired BBB; microglial activation;	Diffuse WML; microglial activation; Impaired BBB	Micro-Hge in some models	BBB changes, neuro-inflammation. Diffuse WML in animals with UCCAo	Focal micro-infarcts; No diffuse WML	A β plaques, hippocampal neuronal loss, gliosis, micro-Hge	WML - vacuolisation; focal lesions in some aged animals

Small vessel changes: Arteriosclerosis, BBB dysfunction, CAA	NA	NR	CAA in some models	NA	CAA, micro-vascular rarefaction; BBB dysfunction in some models	BBB dysfunction (some studies)	Increased tortuosity	CAA. BBB dysfunction (on MRI)	GOM deposits, impaired CVR; BBB dysfunction (some studies)
---	----	----	--------------------	----	---	--------------------------------	----------------------	-------------------------------	--

Clinical and pathological aspects of VCI are summarised in the first column. How selected animal models relate to these is summarised in the succeeding columns.

Abbreviations. BBB: blood-brain-barrier. CVR: cerebrovascular reactivity. GOM: granular osmiophilic material. Hge: haemorrhage. HHCy: hyperhomocysteinemia. HT: hypertension. NA: not applicable. NR: not reported. SHRSP: stroke-prone spontaneously hypertensive rats. UCCAO: unilateral common carotid artery occlusion. WML: white matter lesions.
