1 **Abstract**

2 Microcephaly with or without chorioretinopathy, lymphedema, or mental retardation
3 (MCLMR, OMIM 152950) is a rare autosomal dominantly inherited syndrome. Mutations in
4 the kinesin family member 11 (*KIF11*) gene have been associated with this condition. We
5 report here a *de novo* novel heterozygous missense mutation in exon 12 of the *KIF11* gene
6 [c.1402T>G, p.(Leu468Val)] in a boy with 22q11.2 microdeletion syndrome. His major
7 features were microcephaly, ventricular septal defect (VSD), congenital lymphedema of the
8 feet, and distinct facial appearance including upslanting palpebral fissures, a broad nose with
9 rounded tip, anteverted nares, long philtrum with thin upper lip, pointed chin, and prominent
10 ears. His right eye was enucleated due to subretinal hemorrhage and retinal detachment at age
11 3 months. Lacunae of chorioretinal atrophy and the pale optic disc were present in the left
12 eye. He also had a *de novo* 1.6 Mb microdeletion in the Di George/VCFS region of
13 chromosome 22q11.2 in SNP-array, which was confirmed by fluorescence *in situ*
14 hybridization analysis. Here, we report, for the first time the co-occurrence of a *KIF11*
15 mutation and 22q11.2 deletion syndrome in a patient with MCLMR.

16

17 **Keywords:** MCLMR, microcephaly, lymphedema, chorioretinal dysplasia, *KIF11*, 22q11.2
18 deletion.

19

1 **Introduction**

2 There was an ongoing debate about the phenotypic overlap between microcephaly,
3 primary lymphedema and chorioretinal dysplasia syndrome (MLCRD; OMIM 152950) and
4 chorioretinal dysplasia, microcephaly and mental retardation syndrome (CDMMR; OMIM
5 156590) [Angle et al., 1994; Feingold and Bartoshesky, 1992; Fryns et al., 1995]. With the
6 identification of causative variants in the kinesin family member 11 (*KIF11*) gene in both
7 MLCRD and CDMMR cases, it was demonstrated that these conditions are allelic with highly
8 variable expression [Ostergaard et al., 2012]. The association of microcephaly with or without
9 chorioretinopathy, lymphedema, or mental retardation is now collectively called MCLMR and
10 merged into one entity (OMIM 152950).

11 The 22q11.2 deletion syndrome (OMIM 188400) is a frequent microdeletion
12 syndrome with an estimated incidence ranging between 1:2000 to 1:7000 live births
13 [Shprintzen, 2008]. The clinical features consist of conotruncal heart malformations, palatal
14 abnormalities, learning difficulties, thymus and parathyroid hypoplasia, and characteristic
15 facial features including short palpebral fissures, hypoplastic ala nasi, bulbous nasal tip, small
16 mouth and chin and overfolded helices [Binenbaum et al., 2008; Forbes et al., 2007].

17 Here, we report a case with MCLMR and 22q11.2 deletion syndrome presenting with
18 overlapping clinical findings.

19 **Subjects and Methods**

20 A 1-year-old boy was referred due to the atypical facies. His healthy parents were non-
21 consanguineous. His birth weight, length, and head circumference (OFC) were 3230 gr (-0.5
22 SD), 50 cm (-0.06 SD), and 30.1 cm (-2.5 SD), respectively. Postnatal echocardiography
23 revealed a perimembranous VSD. Because of bilateral edema of the dorsum of the feet,
24 lymphoscintigraphy was performed. There was no evidence of uptake of tracer in the inguinal
25

1 lymph nodes or lymphatic tracts confirming the primary lymphedema. The result is typical of
2 the functional aplasia typically observed in MCLMR [Ostergaard et al., 2012]. Due to the
3 prediagnosis of retinoblastoma, his right eye was enucleated and fitted with a prosthetic eye at
4 age 3 months. Pathological examination of the right eye revealed diffuse retinal detachment
5 and subretinal hemorrhage.

6 On his examination at 1-year-old, he had microcephaly (OFC: 38 cm, -6.7 SD),
7 prominent ears, upslanting palpebral fissures, a broad nose with rounded tip, anteverted nares,
8 long philtrum with thin upper lip, high arched palate, micro-retrognathia, and congenital
9 lymphedema of the feet (Fig. 1A, B). He achieved head control, sitting, and walking at 2, 8,
10 and 12 months, respectively. Complete blood count, calcium metabolism, thyroid functions,
11 immunoglobulins and T lymphocyte subsets were in normal range. Echocardiography
12 revealed spontaneous closure of the VSD. No venous insufficiency in lower extremities was
13 seen via venous Doppler. Cranial MRI revealed microcephaly without any structural
14 abnormalities. Fundoscopic examination of the left eye revealed the pale optic disc and
15 lacunar chorioretinal atrophy. Electroretinography showed generalized rod-cone dysfunction.
16 Hearing test was normal. Developmental quotient of Denver II Developmental Test at age 6,
17 was 60. He had hyperactive behavior and attention problems but could speak in long
18 sentences fluently by age 6. He has been followed up regularly and was 8 years old at the last
19 examination. During the follow-up period, his growth parameters (height and weight) were
20 normal. At 8 years of age, his weight and length were 20 kg (-1.89 SD) and 122 cm (-1.04
21 SD), respectively. However, his OFC was 45 cm (-5.3 SD) (Fig. 1C, D). The findings of the
22 left fundus remained the same. He had low visual acuity and could count fingers at 2 meters.
23 His OCT imaging revealed severe retinal thinning. The bilateral lymphedema remained more
24 pronounced on the right foot (Fig. 1E).

1 For detection of copy number aberrations, Human CytoSNP-12 bead chip array
2 (Illumina) which contains approximately 300.000 SNPs per sample was used with a targeted
3 and overall resolution of 62 KB and 72 KB, respectively. Fluorescence *in situ* hybridization
4 analysis (FISH) was carried out using the standard probe (Di George/VCFS TUPLE 1) for
5 22q11.2 deletion. MCLMR was suspected based on the retinal detachment history,
6 microcephaly, pale optic disc, chorioretinal atrophy and congenital lymphedema. Direct
7 sequencing of all 22 exons and flanking introns of *KIF11* was performed using methods
8 described previously [Ostergaard et al., 2012]. Pathogenicity and potential functional effects
9 of detected variants in *KIF11* were assessed using Mutation Taster and SIFT prediction tools
10 [Schwarz et al., 2010; Kumar et al., 2009].

11

12 **Results**

13 The karyotype analysis was normal (46,XY). SNP-array analysis detected a *de novo*
14 1.6 Mb microdeletion in the Di George/VCFS region of the 22q11.2 locus (Fig. 2A), which
15 was confirmed by FISH (Fig. 2B). The SNP-array analysis showed no additional pathological
16 CNVs. A *de novo* heterozygous missense mutation in exon 12 of the *KIF11* gene
17 (NM_004523: c.1402T>G; p.Leu468Val) was detected (Fig. 2C-E). The variant is predicted
18 pathogenic according to Mutation Taster (probability>0.9999) and SIFT (SIFT score: 0.03)
19 and has not been observed in 1000 Genome Project (<http://www.internationalgenome.org/>) or
20 Genome Aggregation (<http://gnomad.broadinstitute.org/>) databases. The variant was
21 submitted to the LOVD database (variant number #72895,
22 <https://databases.lovd.nl/shared/genes/KIF11>).

23

24

25

1 **Discussion**

2 *KIF11* encodes a homotetrameric protein, EG5, that drives microtubule sliding and
3 contributes to the assembly of the mitotic spindle [Jones et al., 2014]. EG5 also has non-
4 mitotic functions such as involvement in endothelial cell lineage proliferation, secretory
5 protein transportation and protein translation [Bartoli et al., 2011; Exertier et al., 2013;
6 Wakana et al., 2013]. EG5 possibly also has a role in the cilia [Birtel et al., 2017].

7 Jones et al. [2014] assessed 37 individuals with *KIF11* mutations and found
8 microcephaly, ocular abnormality, lymphedema, epilepsy, and cardiac anomaly as major
9 clinical features. The OFCs of the patients were ranging from -9.5 to -1.1 SDs. Similarly,
10 Robitaille et al. [2014] reported a *KIF11* mutation-positive patient with microcephaly (OFC: -
11 4 SD), bilateral chorioretinal atrophy and retinal detachment. Her mother, with the same
12 mutation, had borderline microcephaly (OFC: -2 SD). However, her eye examination
13 remained normal, indicating variable expression of the condition.

14 In the study of Jones et al. [2014], major ocular abnormalities were chorioretinopathy,
15 hypermetropia, myopia, bilateral retinal folds and microphthalmia. Lacunar chorioretinopathy
16 was found in approximately 60% of the patients. Balikova et al. [2016] showed generalized
17 rod-cone and severe macular dysfunction in seven, optic disc pallor in three patients with
18 *KIF11* mutations. Their long-term observation of three of the *KIF11* mutation positive
19 patients with chorioretinal atrophy over 2, 6 and 9 years revealed no progression of fundus
20 examinations. Consistently in our patient, focal areas of lacunar chorioretinal atrophy and
21 optic atrophy were observed. Electroretinography showed generalized rod-cone dysfunction.
22 He had unilateral retinal detachment and a history of enucleation because of the prediagnosis
23 of retinoblastoma. During his follow-up, the findings of the left fundus remained the same.
24 Therefore, we highlight that, eye findings of the condition may resemble retinoblastoma.

1 The lymphedema seen in *KIF11* mutations is described as congenital, bilateral and
2 confined to the dorsa of the feet. However, adult onset and intermittent lymphedema were
3 also reported [Jones et al., 2014]. Interestingly, a very recent study has reported primary
4 lymphedema of lower limbs in four patients with 22q11.2 deletion syndrome [Unolt et al.,
5 2018]. Unlike the patients with MCLMR, the lymphedema in these patients was not confined
6 to the feet and extended to the calves in one and to the thighs in three patients. The patient
7 presented here had a bilateral and pedal congenital lymphedema typical of that seen in other
8 MCLMR cases. Thus, we have considered that congenital lymphedema in our patient is
9 related to the *KIF11* mutation rather than the 22q11.2 deletion syndrome.

10 The characteristic facial phenotype of *KIF11* mutations was described as upslanting
11 palpebral fissures, broad nose with rounded tip, long philtrum with thin upper lip and
12 prominent ears [Jones et al., 2014]. Since bulbous nasal tip, small mouth and chin are
13 common features of the 22q11.2 deletion syndrome [Binenbaum et al., 2008], we have
14 postulated that the facial features of our patient are in association with both conditions.

15 In the MCLMR review, 8% of the patients had cardiac anomalies including patent
16 foramen ovale, thickened pulmonary valve, hypertrophic cardiomyopathy and atrial septal
17 defect [Jones et al., 2014]. We have considered that VSD in our patient is related to the
18 22q11.2 deletion rather than the *KIF11* mutation. The common findings of 22q11.2 deletion
19 syndrome, including thymus and parathyroid hypoplasia, hearing loss were not present in the
20 patient.

21 Recent observational WES studies have found that approximately 5% of patients were
22 carriers of two gene defects. Diagnosing the cases with dual molecular findings can be
23 difficult especially if the phenotypes overlap [Yang et al., 2014; Posey et al., 2017]. As the
24 22q11.2 deletion did not explain the whole clinical picture of our proband, MCLMR was
25 suspected based on the microcephaly, eye problems and congenital lymphedema and a novel

1 *de novo* variant in *KIF11* was identified. We propose that these two genetic syndromes are the
2 cause of the mixed phenotype of the patient.

3 In conclusion, we have identified in a patient the association of 22q11.2 deletion
4 syndrome and *KIF11* mutation for the first time and discussed the overlapping clinical
5 findings such as distinct facial appearance, VSD as well as microcephaly, congenital
6 lymphedema and chorioretinopathy.

7

8 **Statement of Ethics**

9 Signed informed consent and the permission for the publication of photos of the
10 patient were obtained from the parents. The data presented in this study was retrieved from
11 the routine clinical care facilities of Cerrahpasa School of Medicine, Istanbul, Turkey.
