## ESTIMATION OF EXPOSURE

The PM<sub>2.5</sub> and ozone exposure estimates used in GBD 2015 are described in detail elsewhere (GBD 2015 Risk Factor Collaborators 2016; Shaddick G. et al. Submitted).

**PM<sub>2.5</sub>** We estimated annual average exposure for five year intervals from 1990 – 2015 at 0.1 x 0.1 ° (~ 11 x 11 km at the equator) resolution throughout the world using a combination of satellite-derived estimates, surface measurements and geographic information. The satellite-based PM<sub>2.5</sub> estimates use multiple (MISR, MODIS Dark Target, MODIS and SeaWiFS Deep Blue, and MODIS MAIAC) satellite aerosol optical depth (AOD) retrievals to estimate near-surface PM<sub>2.5</sub> by applying the relationship of PM<sub>2.5</sub> to AOD simulated by the GEOS-Chem chemical transport model (Van Donkelaar et al. 2016). Estimates for 1995 and 1990 were based on the ratio of GEOS-Chem simulations using anthropogenic emissions between 2005 and the respective year of interest, but constant meteorology. Satellite-based estimates, and quantities estimated using GEOS-Chem were available for 1990, 1995, 2000, 2005, 2010, 2011, 2012, 2013 and 2014.

The GBD 2015 update incorporated more recent ground measurement data, and also including additional locations where measurement data have become available. These updates were made in collaboration with the World Health Organization (WHO) and included within the 2016 release of the [WHO Global Urban Ambient Air Pollution Database](#). Monitor-specific measurements (rather than the city averages as reported in the WHO database) were used, resulting in measurements of annual average concentrations of PM<sub>10</sub> and PM<sub>2.5</sub> from 6,003 ground monitors. The majority of measurements were recorded in 2014 (as there is a lag in reporting measurements, little data from 2015 were available). Where data were not available for 2014 (2760 monitors), data were used from 2015 (18 monitors), 2013 (2155), 2012 (564), 2011 (60), 2010 (375), 2009 (49), 2008 (21) and 2006 (1). For locations measuring only PM<sub>10</sub>, PM<sub>2.5</sub> measurements were estimated from PM<sub>10</sub>. This was performed using a locally derived conversion factor (PM<sub>2.5</sub>/PM<sub>10</sub> ratio, for stations where measurements are available for the same year) that was estimated using population-weighted averages of location-specific conversion factors for the country. If country-level conversion factors were not available, the average of country-level conversion factors within a region were used. As in the GBD2013 database, additional information related to the ground measurements was also included where available (e.g. monitor geo coordinates, monitor site type).

Significant advances were incorporated in the methodology used to combine data from multiple sources since GBD 2013. In GBD 2010 and GBD 2013, exposure estimates were obtained using a single global function to calibrate available ground measurements to a ‘fused’ estimate of PM<sub>2.5</sub>; the mean of satellite-based estimates and those from the TM5 chemical transport model, calculated for each 0.1°x0.1° grid cell. This was recognized to represent a trade-off between accuracy (see discussion in Brauer et al. 2016) and computationally efficiency when utilising available data sources.

In GBD 2015 we conducted formal model evaluation to compare the single global calibration function as in GBD 2013, a geographically-weighted regression (van Donkelaar et al. 2016), and a Bayesian Hierarchical Model (BHM), with the BHM ultimately used for analysis based on formal model evaluation results. The BHM framework allows for the estimation of country-specific coefficients in the calibration

model. Where data were insufficient within a country, information was 'borrowed' from a higher aggregation (region or super-region). Uncertainty is also propagated through the model to comprise a posterior distribution for each grid cell, rather than just a single point estimate. Due to both the complexity of the models and the number of spatial predictions that were required, 'approximate' Bayesian inference based on integrated nested Laplace approximations (INLA) were used (R-INLA).

Model development and evaluation was performed using within- and out-of-sample assessment. In the evaluation, cross validation was performed using 25 combinations of training (80%) and validation (20%) datasets. Validation sets were obtained by taking a stratified random sample, using sampling probabilities based on the cross-tabulation of PM<sub>2.5</sub> concentration measurement categories (0-24.9, 25-49.9, 50-74.9, 75-99.9, 100+  $\mu\text{g}/\text{m}^3$ ) and super-regions, resulting in them having the same distribution of PM<sub>2.5</sub> concentrations and super-regions as the overall set of measurement sites. Modelling was performed on the log-scale with the unit of measurement being a grid cell. Variable selection was based on contribution to model fit (DIC, a measure of the relative quality of a model and closely related to that of AIC but for Bayesian models) and predictive ability.

Variables and model structures that were considered in model development included:

(SAT) Estimate of PM<sub>2.5</sub> (in  $\mu\text{g}/\text{m}^3$ ) for 2014 from satellite remote sensing on the log-scale.

(CTM) Estimate of PM<sub>2.5</sub> (in  $\mu\text{g}/\text{m}^3$ ) for 2014 from the TM5 chemical transport model on the log-scale.

(POP) Estimate of population for 2014 on the log-scale.

(SNAOC) Estimate of the sum of sulfate, nitrate, ammonium and organic carbon simulated using the GEOS Chem chemical transport model

(DST) Estimate of compositional concentrations of for mineral dust simulated using the GEOS Chem chemical transport model

(EDxDU) The log of the elevation difference between the elevation at the ground measurement location and the mean elevation within the GEOS Chem simulation grid cell multiplied by the inverse distance to the nearest urban land surface

(LOC) Binary variable indicating whether the exact location of ground measurement was known

(TYPE) Binary variable indicating whether exact type of ground monitoring site was known

(CONV) Binary variable indicating whether ground measurement was PM<sub>2.5</sub> or converted from PM<sub>10</sub>

Random Effects were included for the intercept to allow for multiple ground monitors in a grid cell, country-region-super-region hierarchical random effects for the intercept, country-region-super-region hierarchical random effects for the coefficient associated with SAT, country-region-super-region hierarchical random effects for the coefficient associated with the difference between estimates from CTM and SAT, country-region-super-region hierarchical random effects for the coefficient associated

with POP, country level random effects for population using a neighbourhood structure allowing specific borrowing of information from neighbouring countries. Within a region, country level effects of SAT and the difference between SAT AND CTM were assumed to be independent and identically distributed. Within a super-region, region level random effects were assumed to be independent and identically distributed. Super-region random effects were assumed to be independent and identically distributed. Interactions between the binary variables and the effects of SAT and CTM were also included.

The final model contained the following variables: SAT, POP, SNAOC, DST, EDxDU, LOC, TYPE, and CONV, together with interactions between SAT and each of LOC, TYPE and CONV. The model structure contained grid cell random effects on the intercept to allow for multiple ground monitors in a grid cell, country-region-super-region hierarchical random effects for intercepts and SAT and country level random effects for population using a neighbourhood structure allowing specific borrowing of information from neighbouring countries together with region-super-region hierarchical random effects for POP. Compared to the model used in GBD 2013, this model showed improved predictions of ground measurements in all super regions and an improvement in both within-sample fit; with an increase in  $R^2$  from 0.64 (reported in GBD 2013) to 0.91, and out-of-sample predictive ability; with a global population-weighted RMSE of 12.1  $\mu\text{g}/\text{m}^3$  compared to 23.1  $\mu\text{g}/\text{m}^3$  when using the GBD 2013 model. Including estimates from the TM5 chemical transport model used in GBD 2013 did not improve the predictive ability of the model and was therefore not included. Because the TM5 simulations used in GBD 2013 included a constant level of contribution from sea salt and windblown mineral dust, these prior estimates obscured temporal trends in dust emissions. This difference, along with a lag in incorporating changes in levels of emissions into the emissions inventories which are inputs to CTM simulations, has led to changes in both the magnitude of exposure and slopes of trends in some countries.

As satellite estimates, populations and quantities estimated using the GEOS-Chem model were only available up to 2014, estimates for 2015, (and associated measures of uncertainty) were obtained by fitting smoothing splines within each cell to the medians and limits of the 95% credible intervals for each cell from 2010 to 2014 and extrapolating to 2015. The smoothing splines were fit within a Generalised Additive Modelling framework with the degrees of freedom calculated for each cell by multivariate generalized cross validation.

**Ozone** As in GBD2013 (Brauer et al. 2016) we used TM5-FASST (Van Dingenen et al. 2014) (FAst Scenario Screening Tool, a reduced-form version of TM5) simulations for 1990, 2000 and 2010, including an updated set of internally consistent emissions inventories and “typical” (year 2001) meteorology, to simulate a running 3-month average (of daily 1 h max values) ozone concentrations for each grid cell over a full year from which we selected the maximum of these values. This metric was chosen to align with epidemiologic studies of chronic exposure which typically employ a seasonal (summer) average, and to account for global variation in the timing of the ozone (summer) season. These estimates were simulated with TM5-FASST at  $0.1^\circ \times 0.1^\circ$  for 1990, 2000 and 2010 using the same emissions and meteorological inputs as for the  $\text{PM}_{2.5}$  simulations. Estimates for 2015 and 2005 were generated by fitting a natural cubic spline to the 1990, 2000 and 2010 estimates and then interpolating (in the case of 2005) and extrapolating (for 2015) from the fitted values.

## Theoretical Minimum Risk Exposure Level

The TMREL was assigned a uniform distribution with lower/upper bounds given by the average of the minimum and 5<sup>th</sup> percentiles of outdoor air pollution cohort studies exposure distributions conducted in North America (Supplement Appendix Table 1 – selected studies indicated in red), with the assumption that current evidence was insufficient to precisely characterize the shape of the concentration-response function below the 5<sup>th</sup> percentile of the exposure distributions. The TMREL was defined as a uniform distribution rather than a fixed value in order to represent the uncertainty regarding the level at which the scientific evidence was consistent with adverse effects of exposure (Lim et al. 2012 Table 1; GBD 2015 Risk Factors Collaborators 2016).

The specific outdoor air pollution cohort studies selected for this averaging were based on the criteria that their 5th percentiles were less than that of the American Cancer Society Cancer Prevention II (CPS II) cohort's 5th percentile of  $8.2 \mu\text{g} / \text{m}^3$  based on Turner et al. (2016). This criteria was selected since GBD2010 (Lim et al., 2012) used the minimum,  $5.8 \mu\text{g} / \text{m}^3$ , and 5th percentile solely from the CPS II cohort. The resulting lower/upper bounds of the distribution for GBD 2015 were  $2.4 \mu\text{g} / \text{m}^3$  and  $5.9 \mu\text{g} / \text{m}^3$ .

The TMREL for ozone was defined similarly using a uniform distribution 33.3–41.9 parts per billion (Lim et al. 2012 Table 1).

## ESTIMATION OF RISK

We estimated the Ambient Air Pollution-attributable burden of disease based on the relation of long-term exposure to PM<sub>2.5</sub> with Ischemic Heart Disease, stroke (ischemic and hemorrhagic), COPD, lung cancer and acute lower respiratory infection and on the relation of long-term exposure to ozone with COPD. These were also the pollutant-outcome pairs used to estimate the Ambient Air Pollution attributable burden in GBD 2010 and 2013. For GBD 2015, we used results from all cohort studies conducted on subjects living in the US and Western Europe (Appendix Table 1). These studies comprised all studies published as of mid-2016 that reported cause-specific relative risk estimates based on measured or modeled PM<sub>2.5</sub> and that adjusted for potential confounding due to other major risk factors such as tobacco smoking using data for each study participant. One exception was (Crouse et al. 2012) that adjusted indirectly for potential confounding effects of smoking and obesity (Appendix Table 1).

For GBD 2013 we added health loss from LRI in adults to the five outcomes previously included in GBD 2010. This decision was taken based on the association between lower respiratory infection and exposure to indoor and ambient particulate air pollution in young children and the results of time-series studies reporting increased morbidity and mortality in adults associated with short-term exposure to ambient particulate air pollution. There is also evidence of adverse effects of exposure to air pollution on host defences and immune function with respect to respiratory infection in adults. The relative risk of LRI in adults was estimated by adding relative risk estimates for active smoking from the study by Doll et al. (1994) to the LRI IER, and this IER was used to estimate the LRI burden attributable to PM<sub>2.5</sub> in both children and adults. For GBD 2015 we added studies on active smoking risk from Bjartveit et al. 2005, Teo et al. 2006, and Pirie et al. 2013.

### Integrated Exposure Response Parameter Estimation

The unknown IER model parameters were estimated in GBD 2010 by first simulating 1000 draws of the input relative risks based on the assumption that their logarithms followed a normal distribution with mean given by the logarithm of the observed relative risk and standard deviation by the corresponding observed standard error. The IER model was fit separately to the 1000 sets of simulated relative risk data by non-linear least squares. This approach was described in detail in Burnett et al. (2014).

A limitation of this method is that the non-linear least squares estimation routine did not converge for all 1000 sets of simulated input relative risk data, raising concerns that only certain patterns in the simulated data would be kept such that the estimation routine would converge. This approach also resulted in a wide range of predicted risk for any given concentration across the 1000 simulated values.

To address these limitations, in GBD 2013, we selected an alternative method to estimate the unknown IER parameters and their uncertainty that also incorporated the uncertainty in the TMREL. The observed relative risks were related to the IER within a Bayesian framework using the computer software package STAN (Stan, 2015). Given the true values of the four parameters  $(\alpha, \beta, \gamma, z_{cf})$  we assumed that the logarithm of the each study's observed relative risk was normally distributed with mean defined by the

IER function, and variance given by the square of the observed standard error of the study-specific log-relative risk estimate. The parameters  $(\alpha, \beta, \gamma)$  were each assumed to have a non-informative gamma distribution independent of each other, each with mean 100 and variance ten thousand. The STAN code used to fit the IER model is given below. However, in order to achieve convergence of the MCMC routine we needed to divide the exposure concentration by 10 billion which resulted in unrealistically narrow confidence intervals. To address this issue for GBD 2015, in addition to adding several new relative risk estimates we expanded the error specification for each logarithm of the observed relative risk to include the sum of the observed sampling error and an additional error parameter that was allowed to vary by source of PM<sub>2.5</sub> (outdoor air, second hand smoke, indoor air, and active smoking). Under these new conditions convergence was achieved without the need to divide concentration by 10 billion. As with GBD 2013, we assume a non-informative gamma prior on the IER parameters with mean 100 and standard deviation of 100.

The specification of the relative risks used as data input to the IER parameter fitting process was also changed from GBD 2013 to GBD 2015. In GBD 2010 and GBD 2013, we constructed a relative risk for outdoor air pollution studies based on the unit risk evaluated at an exposure contrast of the study mean to the TMREL. In GBD 2015 we altered the contrast to represent the 95<sup>th</sup> to 5<sup>th</sup> percentiles of the exposure distribution as for some studies their 5<sup>th</sup> percentiles was much larger than the TMREL. We therefore were not extrapolating evidence from any study beyond their observed exposure range.

### Relative risk estimate for Ozone

The GBD 2013 estimate (and the earlier GBD 2010 estimate reported by Lim S et al. 2012) used a log-linear concentration-response relationship for aggregated respiratory causes of death (460-519 ICD 9) reported by Jerrett et al. (2009) for the American Cancer Society (ACS) study that was robust to inclusion of PM<sub>2.5</sub>, confounders and choice of analytic model. Estimates of annual average exposure to ozone were based on daily average maximum ozone levels from April through September reported by US EPA ground-level monitors. We used the estimate from a single pollutant model: RR=1.029 per 10 ppb (95% CI 1.010-1.048) (Jerrett et al. 2009, Table 3). In a subsequent unpublished analysis of conducted by Jerrett and colleagues the estimate for COPD ([490-496 ICD 9) in these data was: RR=1.027 per 10 ppb (95%CI 1.002-1.053) (Richard T Burnett, personal communication).

## PM<sub>2.5</sub> Attributable YLD estimation

In order to estimate the DALYs attributable to ambient air pollution the fitted IERs were used to estimate the attributable YLL for all causes of health loss related to ambient air pollution. Since relative risks of both incidence and mortality were used to fit the IER curves for LRI, lung cancer, and COPD, RRs generated from these curves were applied evenly to produce estimates of YLL and Years of Life with Disability (YLD). For cardiovascular outcomes, the effect of air pollution is known to be significantly different for morbidity and mortality, therefore to estimate the YLD the fitted IERs were then re-scaled for IHD and stroke based on the ratio of excess relative risk of IHD and stroke incidence (as indicator of morbidity) and mortality in several major cohort studies.

In order to scale the YLDs for ambient air pollution, we used a ratio of the excess relative risk reported in three cohort studies (Miller et al. 2007; Lipsett et al. 2011; Puett et al. 2009) that reported mortality and incidence relative risks for IHD and stroke.

The ratio was applied as:

$$RR = \text{ratio} * IER(\text{PM}_{2.5}) - \text{ratio} + 1$$

Or more simply:

$$RR_c = \text{ratio} * RR_m - \text{ratio} + 1$$

Stroke morbidity ratio: 0.553

IHD morbidity ratio: 0.141

All others: 1

Formula:

$$(RR_c - 1) / (RR_m - 1) = \text{Ratio}$$

### Stroke

Miller et al. (2007):  $(1.28 - 1) / (1.82 - 1) = 0.341$

Lipsett et al. (2011):  $(1.13 - 1) / (1.17 - 1) = 0.765$

Avg: 0.553

### IHD

Miller et al. (2007):  $(1.21 - 1) / (2.21 - 1) = 0.174$

Puett et al. (2009):  $(1.11 - 1) / (2.02 - 1) = 0.108$

Avg: 0.141

## ESTIMATION OF POPULATION ATTRIBUTABLE FRACTION (PAF) AND BURDEN

The numbers of DALYs and deaths attributable to ambient air pollution were calculated by applying the year-, location-, age- and sex-specific PAF to the numbers of DALYS and deaths, which were estimated as part of GBD 2015 (GBD 2015 Risk Factor Collaborators 2016). GBD 2015 included an expansion of countries for which we disaggregated our estimates at the subnational level. At the first level of subnational division, 256 geographic units were included in GBD 2015. For this paper we present results for the 195 national and territory-level geographies.

Cause-specific mortality for IHD, stroke, COPD, lung cancer and acute respiratory infections were estimated from vital registration and verbal autopsy data. YLLs due to each cause death were calculated by summing the number of years lost by due to death at a given age compared with reference standard population life expectancy. In addition, the prevalence of more than 1000 sequelae of the different causes were estimated by a Bayesian hierarchical model. YLDs were calculated as a product of prevalence of each sequela and the sequela's disability weight. Total burden was summarized in terms of DALYs by adding YLLs and total YLDs for each cause. Detailed descriptions of death and DALY estimation methods and results and the calculation of the PAF have been published elsewhere (GBD 2015 Mortality and Cause of Death Collaborators, 2016; GBD 2015 DALYs and HALE Collaborators, 2016; GBD 2015 Risk Factor Collaborators, 2016; GBD 2015 Disease and Injury Incidence and Prevalence Collaborators, 2016).

The relative risk for each cause was calculated at the PM<sub>2.5</sub> exposure grid-cell level from the IER.

The location-specific PAF is the proportion of outcomes, for example deaths from lung cancer, attributable to long-term exposure to ambient air pollution at a level greater than the TMREL. Because estimated death and DALYs were not available at the grid-cell level the country level (or subnational unit) PAFs were calculated using gridded population data and estimated as in Equation 1 below:

$$\text{Eq. 1: } PAF = 1 - \frac{1}{\frac{\sum Pop_i * (1/(1-paf_i))}{\sum Pop_i}}$$

Where  $Pop_{io}$  is population and  $paf_{io}$  is the PAF of outcome  $o$  in grid cell  $i$ .

To calculate total burden attributable to ambient air pollution is:

$$AB = \sum_{o=1}^w DALY_o PAF_o$$

To compare the level of burden over time and among countries, different measures were calculated and reported, including: total number for all-age and by age, by sex and combined, all-age per person rate and also age standardized rate of death, DALYS, YLLs and YLDs. The WHO standard population was used to calculate age standardized deaths and DALYs per capita for every country. To preserve uncertainty of estimates for each step of analysis, we kept 1000 samples of posterior distribution for each step and used in later steps up to final results.

## DECOMPOSITION OF GLOBAL TRENDS IN PM<sub>2.5</sub>-ATTRIBUTABLE MORTALITY

Four factors - population growth, population aging, mortality rates independent of exposure to PM<sub>2.5</sub>, and exposure to ambient PM<sub>2.5</sub> - contribute to the total mortality attributable to ambient PM<sub>2.5</sub> and the changes in these factors contributes to the overall change in attributable mortality. We calculated the contribution of changes in each of these factors to the net change in mortality attributable to ambient PM<sub>2.5</sub> between 1990 and 2015. The algorithm estimates the contribution from each factor incrementally. Following GBD 2015 decomposition of attributable burden, we used a method developed by Das Gupta to calculate average of each factor effect through all sequences of the four factors. For example for a sequence: first the increase due to population size (population growth), then the change in the age structure of the population (population aging), followed by the change in the rate of mortality unrelated to ambient PM<sub>2.5</sub> exposure (change in rate due to changes in access to care, treatment and other risk factors), and finally the change in exposure were calculated. The difference between every consecutive step is an estimate of the contribution of each factor.

$$A = \sum_{a=1}^{80+} Pop2015_a * \frac{\sum_{a=1}^{80+} (R1990_a * Pop1990_a)}{\sum_{a=1}^{80+} (Pop1990_a)} * All_{agePaf_{1990}}$$

$$B = \sum_{a=1}^{80+} (R1990_a * Pop2015_a * Paf1990_a)$$

$$C = \sum_{a=1}^{80+} \left( Pop2015_a * R2015_a * \left( \frac{(1 - Paf2015_a)}{1 - Paf1990_a} \right) * Paf1990_a \right)$$

Where, R=the cause-specific rate of mortality; PAF=the population attributable fraction; Pop: Population; a=age group

Population growth effect (%) = (A – total attributable burden in 1990) / total attributable burden in 1990

Population aging effect (%) = (B – A) / total attributable burden in 1990

Baseline rate change effect (%) = (C – B) / total attributable burden in 1990

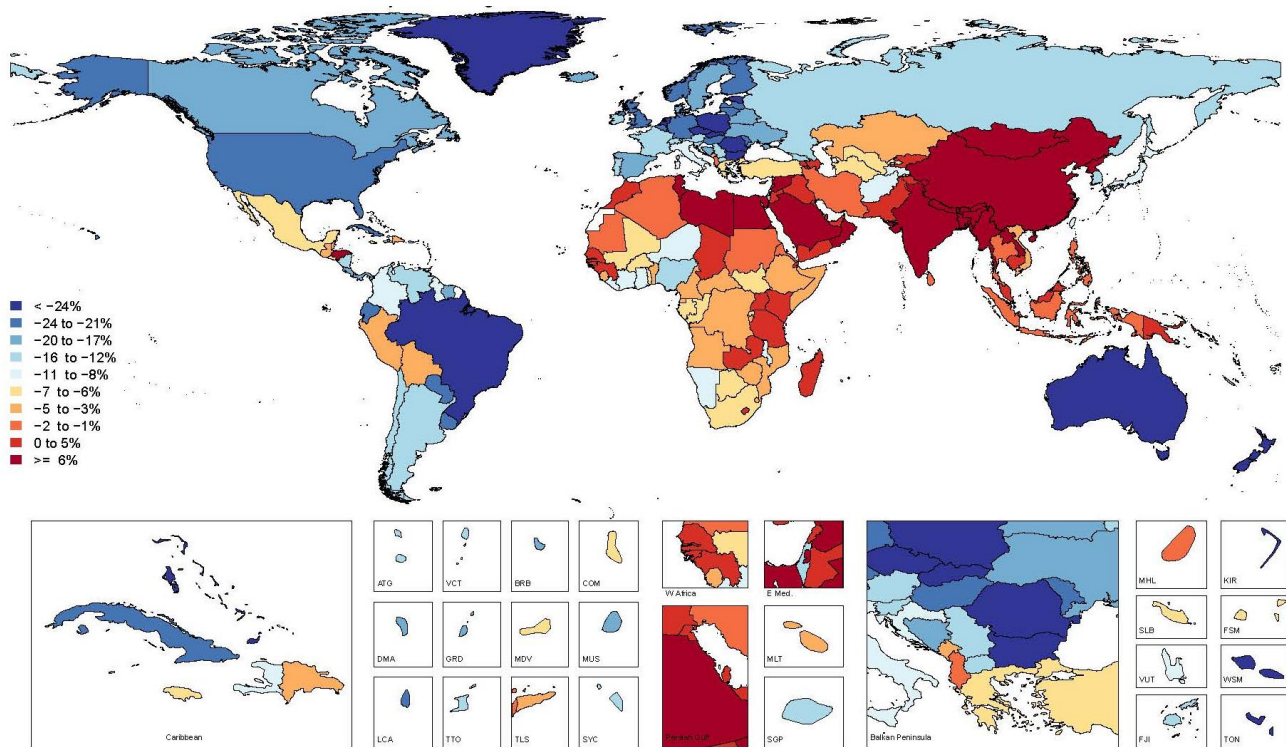

Exposure change effect (%) = (total attributable burden in 2015 – C) / total attributable burden in 1990

Total change (%) = (total attributable burden in 2015 - total attributable burden in 1990)/ total attributable burden in 1990
