Received 1 February 2022; first decision 8 April 2022; accepted 29 July 2022; online publish-ahead-of-print 5 August 2022

Background
Mortality from myocardial infarction (MI) has been decreasing since the introduction of primary percutaneous intervention. Late complications still pose a dilemma, such as deterioration of left ventricle (LV) function, LV aneurysms, and LV thrombus formation. If not adequately managed in a timely manner, this can result in life-threatening consequences. Restoration of LV function by surgical resection of the infarcted LV wall is an option for a few complicated cases, with variable outcomes.

Case summary
A 66-year-old man presented with dyspnoea 2 years after his initial MI, which was treated with a drug-eluting stent to his left circumflex artery. His Warfarin had been stopped after 6 months of treatment of a small LV thrombus, which was noted at the time of his initial infarction. His echocardiogram on admission demonstrated severe LV systolic impairment of 23% (which had deteriorated from 40%) with a giant true aneurysm of the basal to mid-lateral wall, which resembled a Valentine heart. The presence of a large, organized thrombus filling the aneurysm complicated the case further. The patient underwent a resection of the LV aneurysm and thrombus. He remained asymptomatic and maintained a significant improvement of his LV function to 47% at his 5 months scan.

Discussion
The importance of imaging post-large MI and follow-up imaging once thrombus resolution has occurred is crucial. Patients with large LV aneurysm associated with severe refractory LV impairment and LV thrombus should be considered for LV aneurysmectomy for prognostic benefit and symptom relief.

Keywords
Aneurysm • Case report • Cardiac magnetic resonance • Left ventricular aneurysmectomy • Myocardial infarction • Thrombus

ESC Curriculum
2.1 Imaging modalities • 2.3 Cardiac magnetic resonance • 3.3 Chronic coronary syndrome • 6.2 Heart failure with reduced ejection fraction • 7.5 Cardiac surgery

Learning points
• Left ventricle (LV) thrombus may reoccur or become chronic if there is a large akinetic segment of the myocardium.
• Left ventricle aneurysmectomy should be discussed as an option in severely impaired LV function with LV thrombus or symptomatic patients.
• Cardiovascular magnetic resonance scans should be considered in large myocardial infarction to confirm resolution of subtle thrombus in severely dilated and impaired LV and for assessment of akinetic walls when LV aneurysmectomy is being considered.

Introduction

Since the introduction of primary percutaneous coronary intervention, mortality from acute myocardial infarction (MI) has decreased. Despite this, left ventricular (LV) failure and LV thrombus is a known complication and a cause of increased mortality after the acute period. Left ventricle thrombus is associated with cerebrovascular accident and systemic thromboembolisms. Previous studies have suggested the incidence of LV thrombus in anterior MI being up to 56%. Although most recent studies suggest a lower incidence of up to 8%. This may be attributable to early reperfusion and the introduction of effective heart failure medication such as angiotension-converting enzyme inhibitors. An anterior ST elevation MI (STEMI), significant LV dysfunction, and microvascular obstruction are major risk factors for LV thrombus formation. The detection of LV thrombus has been reported to be higher with cardiovascular magnetic resonance (CMR) compared with echocardiogram, which often patients do not routinely have post-discharge. Missing a late formation LV thrombus could have life-threatening consequences to the patient and the association with LV aneurysms poses a debate of whether medical or surgical approach should be considered.

Case presentation

A 66-year-old male with a past medical history of Type 2 diabetes and hypertension was transferred to the Cardiothoracic Unit with worsening breathlessness. The patient had previously presented 2 years ago with chest pain and was diagnosed with a large MI due to a co-dominant left circumflex artery (LCx) occlusion, which was treated with a drug-eluting stent. He was noted at the time to have severe LV impairment and a small laminar thrombus on echocardiogram and a dual pathology for his severe LV impairment was considered at the time with a plan for an outpatient CMR, which did not occur. He was medically optimized, for heart failure, anticoagulated, and his EF had increased to 40%. According to the patient, he had been advised to stop his anticoagulation after 6 months and there had been no further plans of re-imaging him. Unfortunately, the patient was lost to follow-up. He had remained compliant on his heart failure medications. Due to multiple unattended appointments, this was his first presentation since his MI.

On clinical examination, he was haemodynamically stable, and his chest was clear, with no peripheral oedema. His admission ECG showed sinus bradycardia, rate of 53 b.p.m. with Q waves in Leads II, V5, and V6. His echocardiogram had shown a deterioration in LV systolic function with EF of 20% despite heart failure medication and a large aneurysmal lateral wall with a large laminar thrombus. The patient was immediately started on anticoagulation with Warfarin.

He underwent an angio gram, which showed an unobstructed left anterior descending artery, moderate to severe LCx ostial disease with mild in-stent restenosis, and mild to moderate stenosis of the small right coronary artery. For further assessment of myocardial viability and thrombus size, the patient underwent a cardiac MRI (CMR). This showed a severely dilated LV with severely impaired LV systolic function (EF 23%), a giant LV aneurysm out pouching from the basal to mid-inferolateral and inferior walls (101 mm width, 64 mm depth with a broad neck of 73 mm), resembling a Valentine heart (Figure 1). There was full thickness infarction of all aneurysmal segments and a large organized, thrombus filling the aneurysm, measuring 90 x 29 mm. The right ventricle was of a normal size and systolic function (EF: 59%). The patient was discussed in the multidisciplinary team (MDT) meeting, and it was deemed that he would benefit from a LV aneurysctomy and thrombectomy for better prognosis and symptom relief. The patient had a successful operation, and he was discharged with no complication. His follow-up echocardiogram showed a normal LV cavity size with improvement of his LV systolic function (EF of 42%) with akinet ic inferolateral and anterolateral walls. He has remained on Warfarin and heart failure medications. A follow-up CMR nearing Valentine’s Day confirmed a significant improvement in his LV function, which had maintained at an EF of 47%, with no evidence of further thrombus. The patient remained in NYHA Class I (Figure 1).

Discussion

The highest risk of LV thrombosis formation is within the first 3 months of a MI. Up to 85–90% of thrombi will be detected in the first 7–14 days but 15% can be detected at the 8–9-week scan interval. Often an echocardiogram scan may not show a clear thrombus or be as sensitive as a CMR scan in its detection. Therefore, CMR should potentially be considered for LV thrombus assessment in high-risk patients but repeating at least the echocardiogram scan during follow-up would be beneficial before considering stopping anticoagulation. The 2017 ESC STEMI guidelines suggest 6 months of anticoagulation for mural thrombus with a repeat echocardiogram to decide on further long-term therapy.

A true LV aneurysm is defined as an area of akinesia, which involves a full wall and protrudes, resulting in a reduced EF. Left ventricle aneurysm and severely impaired apical segments are associated with higher risk of thrombus formation. The main aim of a LV aneurysctomy is to re-establish LV structure by removal of akinetic fibrous segments with the intention of decreasing end-diastolic volume and hence increasing stroke volume, ultimately improving mortality and morbidity outcome. There is little data on the beneficial impact of LV aneurysctomy and previous studies such as the STITCH trial did not show
Mending the broken valentine heart

**Figure 1** Cardiovascular magnetic resonance images taken before left ventricle aneurysmectomy. (A and B) Four-chamber and three-chamber long axis demonstrating a giant true aneurysm (white arrow) from the inferolateral wall and inferior wall. Large aneurysm filled with a large thrombus (white star); (C) short axis view of early gadolinium images highlighting thrombus (white star); (D) short axis view of late gadolinium images highlighting infarcted area (white dashed arrow) and thrombus (white star).

**Figure 2** Cardiovascular magnetic resonance images taken after the left ventricle aneurysmectomy. (A and B) Four-chamber and three-chamber long axis demonstrating resection of the aneurysmal wall (white arrow) with presence of probable organized haematoma (white star); (C) long axis four-chamber view of early gadolinium images highlighting no evidence of a thrombus; (D) short axis view of late gadolinium images highlighting the reconstructed new inferolateral wall and infarcted area (white dashed arrow).
